The autopsy held on the Filipino boy gave the following: Age, about twelve years; height, four feet six inches; hair and eyes, black in color; rigor mortis quite well marked; few recent cuts, averaging three inches long, extending through integument, on top of head; pupils dilated equally and normally; axillary glands shotty; lungs normal, generally, though small tuberculous nodule in left apex and few pleuritic bands on the left side; heart, normal in size; number of small subpericardial hemorrhages seen on anterior and posterior surfaces of this organ. Ecchymoses of serous membranes generally throughout body. Spleen normal in size and capsule peeled readily. Liver enlarged, showing two areas of fatty degeneration on its anterior surface, some two and a half to three inches in diameter. Mucosa of stomach and alimentary track congested. Bladder distended with urine. Kidneys: the left shows fetal marking, stellate veins engorged, cortex normal, malpigian bodies seen with naked eye, some congestion of kidney substance; capsule strips readily. We see here clearly that the axillary glands form buboes of the second order and the infection has taken place from the primary inguinal bubo through the lymphatics of that side. Acruro inguinal lymphatic gland of left side is the primary seat of disease in this case. The glands are hypertrophied, engorged, hemorrhagic, and a chain of second-order glands is seen extending up to the common iliacs to the abdominal aorta, and downward, along the crural sheath. Associated with these buboes of the second order is a well-marked œdema, extending retroperitoneally upward to the diaphragm on the left side, and downward toward the apex of Scarpa's triangle. This œdema has the jelly-like appearance so peculiarly characteristic of plague. Cut sections through the œdematous tissues show these structures to be of straw-colored, gelatinous consistency, which yields light amber-colored fluid. The lymphatics and blood vessels in this region are widely distended, and the tissues immediately surrounding the bubo is infiltrated with small, round cells and some leucocytes, as shown by microscopic examination. Smear preparations from the blood, spleen, liver, and buboes almost invariably show the bacillus in pure culture, if the autopsy be made immediately after death; whereas a delay of twenty-four hours or more shows, by microscopical examination, a mixed infection, indicating the presence of secondary invaders. In cultures taken from the blood in the living, especially during the septicæmic or bacteræmic stage of the disease, is this true, for here I found pus organisms in a large percentage of cases, both staphylococci and streptococci. This boy gives a history of having been sick two days, being in a delirious condition when brought to the Pest Camp, and, while *en route*, fell out of the ambulance and suffered the cuts upon scalp mentioned in a utopsyprotocol.

Where were the portals of infection in these two cases? This, I fear, will never be answered. Experiments show that this disease is both infectious

and contagious, though the bacillus being non-spore forming, may disprove the contagion theory. The laboring Chinamen in the tropics invariably go without shoes, and while we know the portals of entry in the skin may be gross or microscopic, these are not characterized by any observable inflammatory action. That some local effect does take place, however, is readily shown in the guinea-pig, where, within a few hours after the introduction of the plague virus, a considerable amount of œdema is apparent around the puncture, and the nearest lymphatic gland is perceptibly swollen. Now if, immediately after death, a cut be made over the point of inoculation, a very red, bloody œdema comes to view, and the nearest lymphatic gland is swollen and full of bacilli. Investigators thus far have all failed to detect any inflammatory changes in the lymphatic vessels connecting the portal of entry with the primary first-order bubo.

It has further been repeatedly demonstrated that plague can be reproduced by feeding rats or mice with pure cultures, or on pieces of the liver or spleen of animals dead of plague. Again, Yersin's experiment of mingling healthy and inoculated mice in the same cage in which the inoculated mice died first, and later the originally healthy, un-inoculated mice succumbing, proves that this disease is not only infectious (inoculable), but communicable by contact or through the atmosphere, to a certain extent. Dissection wounds located on the hands have resulted in the death of some few investigators. Laboratory experimenters have died in some instances from plague, notably those at Vienna. The case occurring in an Ann Arbor medical student, reported by Professor Novy, did not result fatally. Physicians and nurses attendant upon the plague-stricken have, as a rule, escaped this dread disease.

The literature affords few exceptions to this statement.

In my visits to the Chinese Pest Hospital at Manila I took no special precautions except to use an antiseptic upon my hands and the soles of my shoes, the latter being made necessary by the vomiting which seemed very common among these patients, and, lacking the usual hospital facilities, was deposited at will upon the floor.

Clinically there are only two kinds of plague, the bubonic and the pneumonic. The symptoms of bubonic plague are dependent upon the type, as to whether mild or severe. The mild or ambulant form is apparently sporadic, non-fatal, and commonly mistaken for mumps, syphilis, malaria, scrofulous, or "climatic" glandular affections. A few of this type were seen by me and were found to have some fever, pain, tenderness and enlargement of glands, muscular weakness, the characteristic plague tongue with creamy white fur in the center and red at the edges and tip, the eyes congested and the speech thick. In the severe type of the disease, besides the buboes in the groin, armpit, or neck at the commencement, there are certain characteristic symptoms. The countenance early portrays anxiety and distress, later apathy; the eyes are red and congested, and these remain widely open, giving the "staring" eye appearance so common in this disorder. In delirium the face is flushed and the physiognomy wild, or in more advanced cases this may give way to an apathetic, vacant expression just prior to dissolution. The speech is peculiarly hesitating and broken, each syllable pronounced in a husky, thick tone, not unlike that of a drunken man. The creamy, white, furred tongue with the clean red tip and edges may later become dry and covered with a yellowish and whitish-brown fur, though the tip and edges remain red and angry.

In a typical case, then, besides the characteristic expression of the face, speech, and tongue, with the presence of a bubo, there are associated general symptoms, such as shivering, nausea, vomiting, high fever, intense general, though usually frontal, headache, tender and painful bubo, staggering gait, congested eyes, anxious expression, the coated tongue with red tip and edges, restlessness, with a roaming desire, dyspnœa, noisy delirium or coma, ending in gradual or sudden failure of the heart. The pulse, which is at first soft and compressible, becomes intermittent and not infrequently dicrotic, and often difficult to count. The tendency to collapse is marked. If the patient lives until the sixth or seventh day, his chances of recovery are greatly increased; if the buboes suppurate, this is about the eighth, and the temperature usually becomes normal about the tenth day.

The lymphatic system seems to be the elective seat of the plague organism, and the most important rôle is played by the glands. Albrecht and Cohn's nomenclature is so convenient and descriptive of the pathological changes occurring in them, that I shall mention it here.

These authorities, according to the sequence of infectivity, divide them into:

Primary buboes of the first order, primary buboes of the second order, and secondary buboes.

The first gland affected, and usually that showing the most change pathologically, is called a primary bubo of the first order.

Other buboes belonging to the same group or chain of glands as the buboes of the primary first order mentioned, and infected through the lymphatic vessels by the passage of the plague bacilli from these, are called primary buboes of the second order.

Glands, however, located in distant parts of the body, but infected through the blood supply, are called secondary buboes.

Buboes of the first order may occur from a few hours to the fifth day, usually, however, they do not appear until the second day. Those of the second order are developed shortly after the first, though in some cases buboes of both orders seem to develop together. As a rule the second-order buboes are not as large as the first, and the œdema and peri-glandular infiltration are always absent, except when these are associated with buboes of the first order. Secondary buboes may include all of the remaining glands of the body, but are not developed until the disease becomes general, or secondary septicæmia occurs. These are not so painful as those of the two orders mentioned; they are always small, freely movable, œdematous, hyperæmic, and sometimes hemorrhagic.

Primary septicæmia or bacteræmia—that is, the passing of the plague bacilli directly into the blood—is not thought to be possible in this disease.

The examination of the blood, then, I found to be of very little diagnostic value, and I was pleased to find this view verified by no less an authority than Professor Haffkine, formerly of the Pasteur Institute, but now in the service of the Indian Government. I had the pleasure of visiting the Old Government House at Parel, in the suburbs of Bombay, last October, and was shown the laboratory and its workings by Professor Haffkine himself. I was given an opportunity of witnessing the manufacture of the prophylactic against plague, which owes its discovery to Haffkine, and has been used so effectively in India. Old Government House was for many years used by the Indian Government for civil purposes, but about four years since it became a hospital, and finally a large part of this was turned over to

Professor Haffkine for a laboratory. I found it to be a very large building of the colonial type, situated in a large grove of tropical trees. One of the largest rooms contained the laboratory apparatus necessary for the production of the prophylactic, which is made, in brief, as follows:

A kilogram of finely chopped goat's meat is placed in a solution of HCl and heated in an autoclave at a pressure of four to five atmospheres for the purpose of making the albumin and peptones. This material, after filtering and neutralization, and the filtrate diluted to three liters, is sterilized, forming the medium on which the pure cultures of the plague bacillus are grown. A flask of this bouillon is now inoculated with the plague material, and the diagnosis of the organism is made through the characteristic stalactite growth first described by Haffkine.

As mentioned, the organism is extremely aerobic and grows luxuriantly on the surface of the bouillon culture, but after eight or ten days sends down long processes into the depths of the bouillon that resemble very much the stalactites from the roof of a grotto. A very characteristic picture is displayed when the culture flask is illuminated by a candle held behind it. After the culture is tested microscopically, it is transferred to a Pasteur flask, from which the large, three-liter flasks are inoculated. I saw hundreds of these flasks on long tables in the large dark room before mentioned, which serves in reality as a large thermostat, by reason of the mean temperature being so high in India. Here they remain until three successive formations of stalactites are obtained, the flasks being well shaken after each successive growth, which complete process takes place in about six weeks.

The cultures are now killed by placing them in a water bath at 60° C. for three hours, when they are transferred to small bottles, tested and dated, ready for use.

Experiments indicate that the precipitate of dead bacteria and the filtrate, or clear fluid, have widely different properties. The precipitate causes a marked local reaction with only slight constitutional phenomena, while injection of the clear fluid or filtrate excites marked constitutional, with slight local, reaction. The whole sterilized culture is used as a vaccine against the plague. Haffkine suggests that two centimeters of the prophylactic be used at a dose, but this may vary with the personal equation of the patient and the virulence of the dead culture. Two injections are usually given with a large hypodermic syringe. The first dose is injected into the subcutanous tissue over the insertion of the deltoid on the left side, while a week or so later the second injection is made over the triceps. The action consists in some elevation of temperature, a feeling of general malaise and headache, but this soon disappears.

An agglutination reaction toward virulent cultures of the organism is obtainable with the serum of all individuals that have been twice inoculated. Professor Haffkine, in order to meet the objections of the high-caste Hindus, is using gluten or like material free from meat extracts in his culture media. The Hindus differing from the Mahommedans in not using meat of any kind.

Haffkine's prophylactic has been used very extensively in India, and is said to have reduced the number attacked from 77 per cent. to 85 per cent., and the death rate 80 per cent. While the Indian Plague Commission reports in favor of the prophylactic, they are of the opinion that the best results can only be secured by more accurate standardization and dosage. Calmette and Salimbini demonstrated during the epidemic at Oporto, Portugal, that during period of immunization in the heated cultures, animals were extremely sensitive to minimum doses of virus rarely fatal for non-vaccinated animals; hence, a person inoculated with a mild attack of plague might have his malady seriously aggravated if he submitted to Haffkine's preventive inoculation, and a fatal result was possible. This, he thinks, explains some cases of rapid death observed in India following these inoculations. Calmette further holds that the lasting power of heated cultures is much less than that of serums, and did not exceed six months.

While Haffkine's remedy is preventive, it is not curative, hence there is at present but one strictly antitoxic or curative remedy, and this is the serum of Yersin-Roux. This is curative and likewise preventive. The method of its preparation is similar to that of the antitoxin of diphtheria, and is as follows. Horses are treated with the progressive increasing doses of the toxins of the plague, prepared by subjecting virulent bouillon cultures of the bacillus pestis to a degree of heat that destroys them. The injections are kept up until all reaction in the animal ceases. Toxins are now administered to the horse intravenously, and supplemented by the intravenous injection of live bouillon cultures. The horse is bled at various times, and experiments now made with the serum against both living and virulent cultures and against the precipitated toxins of the organism. When the serum has reached the strength where a does of 10 c.c. will protect a mouse of twenty-five grams weight against the living cultures and three times the mortal dose of toxin, it is now considered to have acquired a full antitoxic strength, and is prophylactic or preventive and antitoxic or curative. The dose is from 30 to 50 c.c. subcutaneously, or half this quantity intravenously. The Yersin-Roux serum seems to have been rejected upon insufficient evidence by the Indian Commission. The value of the serum, aside from the claims of the discoverers, is incontestable. The French Commission, upon investigation, determined that mortality was only 14 per cent. in cases treated with serum during the Oporto epidemic, while in those not treated it reached 70 per cent. In Professor Novy's case—the Ann Arbor medical student—the Yersin serum acted as a specific. The quantity used in twenty-four hours after the student was first seen was 120 c.c., one-half of which was injected intravenously. If I should acquire plague at any time, my desire would be to have the Yersin-Roux treatment.

Lustig's vaccine and serum are not as efficacious as the Yersin-Roux serum. They are based on the observation made by Lustig that a nucleo-proteid isolated from the bodies of plague microbes has immunizing properties when injected into animals. The bacilli are grown on agar plates, scraped off, and dissolved in a solution of caustic potash. The nucleo-proteid is now precipitated by acidifying the solution. It may be used, or an antitoxin serum may be obtained, by injecting it into horses. The value of Lustig's discovery is not great, as in 479 cases the percentage of recovery was only 39 per cent.

The treatment of plague, aside from the use of the Yersin-Roux serum, is symptomatic. During the epidemic in Poona, India, treatment consisted chiefly in an administration of stimulants. Ice was used to relieve the pain of buboes. At the Mahratta Hospital, Bombay, that in vogue was four drops of a one-per-cent. solution of atropine every few hours until the effects were observed in the pupils. This, it is said, clears up the tongue and has a general beneficial effect upon the patient.

Manson holds that in relieving symptoms the asthenic tendencies of the disease must be born in mind and depressant remedies of all kinds carefully avoided. He suggests ice-bags to the head and neck, during earlier stages when headache and high fever are present. Also prefers sponging the body hourly with warm water, rather than the employment of antipyretics. Lawson alleviates the vomiting by means of a full dose of calomel, followed by a saline. If this is not successful, or if diarrhœa be present, he recommends ice pills and a mixture of morphine and hydrocyanic acid; sinapisms to the epigastrium are also used. Later, when the pulse begins to fail, strychnia is the main reliance; indeed, Lawson says it should be used in all cases as a routine treatment, and commenced early in the disease. In collapse, various kinds of stimulants, including strong ammonia to nostrils and ether hypodermically. Morphine is the best hypnotic. For buboes in early stage, Manson suggests glycerin and belladonna. When red and inflamed, poultices, and on softening, incision and iodoform dressing. Iodine liniment for indolent buboes. Feeding and stimulation governed by usual indications. The death rate among Chinamen and Filipinos at Manila since the alleged introduction of plague in 1899 is reported to be 79.4 per cent. up to January last; that is, 618 deaths out of 778 cases. My case book for April, 1901, shows nineteen deaths in the fifteen days between April 2 and 16, inclusive, among the Chinese in Chinese Pest Hospital. The mortality of the disease is well known to be governed by racial cleanliness and the hygienic conditions in vogue. The death rate in epidemics may be anything between 40 and 95 per cent. The recent Hongkong epidemic gave a showing of 93.4 per cent. among Chinamen; 77 per cent. is reported among the natives of India; 60 per cent. among the Japanese, and 18.2 per cent. among Europeans. The recent epidemic in Portugal is said to have increased the European mortality to 40 per cent.

It should be understood that the mortality among Chinamen is greater than among the Filipinos. A knowledge of the habits, mode of life, environment, etc., is absolutely necessary to a proper understanding of the question as it affects the inhabitants of the Philippine Islands, and particularly its chief port and metropolis—Manila. Manila is said to have a population of 244,732 souls, exclusive of officers and men of our Army and Navy; of these it is estimated that the Chinese number 51,567, Filipinos, 81,361; Americans, 8,461; Spaniards, 2,382; and 961 scattered among seventeen other nationalities. Chinamen here are divided into a commercial and coolie class; the former are well-to-do, the latter very poor. The rich merchant lives well, while the small shopkeeper and coolie eke out a miserable existence in dark illy-ventilated houses with earthern floors, being, as a rule, poorly fed, badly nourished, and usually unwashed. The Filipinos, on the other hand, live in houses raised upon piles, a variable height above the ground, constructed of bamboo and nipa palm, with a cogon grass roof—here the ventilation is nearly perfect and light and air have full play. These nipa huts, or shacks, form the abiding place, then, of nine-tenths of all Filipinos, and, while they possess certain advantages for health, have, in many instances, dirty, filthy surroundings. Life in the tropics would hardly be bearable without those universal scavengers, the hog and the ant, coming actively to the rescue. The difference, in a word, between the Chinaman and Filipino of the lower class is, that the Filipino is the less dirty of the two. I am satisfied that the plague-stricken Filipinos, thus far, have been those living in close contact with Chinamen, as the number of Filipino women married to the "Chino" class is said to be large, and, aside from this, commercial interests cause much intermingling of the races.

Plague, I believe, has existed in Manila from time immemorial, but the Spanish physicians have called it by other names, and as the Chinamen are practically the property owners of the city, they will not change their mode of living nor the character of the houses they build for habitations and trade purposes. The Chinese shopkeeper usually sleeps, in fact lives, in the same room where his wares are exposed for sale, the only difference being that at night he closes his shop securely for fear of robbery, at the same time shutting out effectually the fresh air.

As stated, the mortality from the pest in Manila for the last three years has reached 79 per cent., and since Yersin has demonstrated the presence of an organism in the earthen floors of pest-infected dwellings, from four to five centimeters below the surface, possessing the morphology, staining, and culture reactions of the plague organism itself, though it is thought non-virulent, may be significant as to the reason why this disorder might continue to prevail.

The local conditions prevailing in Manila are similar, but in less degree, to those seen in India and Egypt, where the surroundings are ideal for the propagation of this pestilence. I was struck particularly with India—its mud huts, without light or air, the filth, overcrowding, and famine pictures. One of the suburbs of Calcutta Howrah, and also Bombay, were most interesting in this regard, as well as the native districts of some of the cities of the northern plain, Lucknow, Agra, and Delhi. Here the native sets to work to plan a home for himself and family; he gets a small plot of ground, which is usually flat, and following the desire of all dwellers in the tropics to build upon piles or elevated ground, he at once proceeds to carry out his plan by throwing the earth together in a heap, forming a small hillock. Upon this diminutive knoll he erects a structure of dried earth, which, while it may possess a door, rarely has a window. The entire building is made of sun-dried clay, as wood is scarce and costly, especially in the north of India. Fuel here consists entirely of dried cow-dung, and brings a fair price in the markets. The excavation left beside the house promptly fills with water at the first rainfall which now forms the drinking supply as well as the family bathing pool. The washing is performed in it weekly, and here the domestic animals disport themselves at will. The pool becomes the home of cholera, and the mud hut the habitat of plague.

This connection of plague with cholera is further emphasized by the recent introduction of the latter disease into the Philippines, where both are now raging. Associated with this is an economic question in India, where plague rages hand in hand with famine, the population being so great, existence so precarious, that while the cost of living has been reduced to three rupees (one dollar of our money) a month, yet many actually starve for want of food. Yet India is a great wheat-growing country, and the annual exports are large, as seen by me at Calcutta, Bombay, and at Kurachee, India's western port at the mouth of the Indus.

Egypt, the most ancient home of plague, if the pestilences described by Manetho are to be considered such, presents a modern picture not unlike that portrayed by India. While the habitations of the Mohammedans of India and those of the Hindus are equally dirty, the Arab and the Egyptian fellah

vie with each other as to who shall live the more filthy.

If Egypt be seen when the valley of the Nile is in flood, and its farmer class driven with the camel, ass, and kine to his hut of dried clay now situated upon the islands and peninsulars formed by the encroaching stream, a picture of squalor, such as is not beheld anywhere else in the world, comes to view. Here, in the most restricted space imaginable, are commingled the native with the domestic animals, so that not infrequently they occupy the same habitation; the resulting conditions productive of disease are not difficult to imagine. The time required for the subsidence of the annual flood is about three or four months. The waters were seen by me in their receding stage, during my visit last fall, which extended to Luxor, 450 miles south of Cairo. Here I found the natives so poor that some of the tombs of ancient Thebes were turned into dwellings for the indigent and needy.

Finally, then, I regard the plague as a cosmic question, governed by hygienic, sanitary, commercial, and, in part, religious considerations. The races, from a pest standpoint, dangerous to the world's well-being, are all located in the Orient, where ignorance, religion, and caste tend to swell the already large mortality list from this disease. While an intelligent quarantine system may modify the death rate and frequently be absolutely preventive, as conducted in many parts of the world, especially Egypt, it is farcical and oftentimes criminal, more especially by reason of the pretended security it exploits so broadly.

I wish to thank Lieutenant William J. Calvert, Assistant Surgeon, U. S. A., for the opportunities extended me in observing some of the cases of plague among Filipinos under his charge at the Pest Camp, Manila.

IMPERATIVE CONCEPTIONS: A STUDY IN DIFFERENTIAL DIAGNOSIS.

By L. HARRISON METTLER, A.M., M.D.,

PROFESSOR OF NERVOUS AND MENTAL DISEASES IN THE CHICAGO CLINICAL SCHOOL; ADJUNCT PROFESSOR OF MEDICINE (NEUROLOGICAL) IN THE COLLEGE OF MEDICINE OF THE UNIVERSITY OF ILLINOIS.

Imperative conceptions or ideas are those involuntary, unrelated, persistent notions that spring up in the minds of many victims of nervous disease. Though found in many states of mental and physical debility, they belong essentially and entirely to the psychoses. They are usually of a depressing, painful, or disagreeable nature, and represent generally unwarranted fears and troublesome doubts. Westphal calls them *compulsive no ions*. Griesinger groups them under the general head of *metaphysical mania*. Le Grand du Saule looks upon them as the expression of a *folie du doute*. Oppenheim names them *imperative ideas* or *notions of restraint*.

The general practitioner should be well acquainted with this symptom of nervous debility, for he will see it in many of his patients whose condition is not serious enough to require consultation with the neurologist or alienist. And yet the diagnosis of the nature and origin of these imperative ideas may determine, to a large extent, the diagnosis of sanity or insanity. In nearly all forms of insanity, impulsive conceptions and fixed ideas, more or less related here to distinct hallucinations, illusions, and delusions, are present. Hence there should always be made a sharp distinction between the imperative conceptions of the sane and of the insane. Probably the most striking difference between them is that in the case of the imperative conceptions of the sane, the patient's judgment remains unimpaired. Knowing that they are bizarre and irrelevant, though persistent, he tries to resist them, and often succeeds in not acting in accordance with their dictates. On the other hand, the imperative conceptions of the insane constitute, for the time being, the patient's very ego. He believes in their actuality and necessity and therefore acts in perfect accordance with their dictates. A neurasthenic who dreads to cross a particular street is the victim of an imperative conception; the man who is convinced that he is ordained by heaven to slay is subject to an insane delusion. In both instances the idea is an imperative one, a sort of delusion, but they differ vastly in degree. In the former the patient laughs at the idea; in the latter he attempts to carry it out to its logical conclusion. It appears, therefore, that it is not the idea itself that is so abnormal or illogical, as it is the patient's judgment in regard to it. The idea may spring out of a thousand real or fancied conditions, and may or may not be reasonable. The chief thing that makes it a valuable sign of mental aberration is the relationship of the patient's reasoning faculty in regard to it. There appeared at my clinic, some time ago, a young man in company with his mother and brother, who had, so far as the one examination revealed, two pronounced imperative or fixed ideas; namely, that he himself was his own brother, always giving his brother's name, age, etc., when asked what his own were, and that this brother was endeavoring to get his property away from him on the ground that he was mentally incompetent to care for it. The second of these ideas may or may not have been an insane delusion; the suspicion or fear may or may not have been well founded. Even granting that the man was insane, it nevertheless might well have been true that the brother in former years did try to get hold of the property and so implanted in the patient's mind the idea which now haunts him. It was impossible, therefore, to say at that time whether this was an insane delusion or a well-founded fear. The former of the two ideas, however—namely, that he was his brother—was very obviously an insane delusion, even in spite of the admitted possibility that the patient may have been trying to identify himself with his brother, so that if insanity were pronounced upon him, it would be the brother who would be sent to the asylum. Paranoiacs are sometimes shrewd enough to reason out such a scheme even as this. And yet, in view of other features in the case, I believe that the patient's false identification was the result of an insane delusion. In regard to this false identification, no amount of reasoning or explanation seemed to shake his belief. In regard to his property being sought after by his brother, he appeared at times to be sensibly impressed that after all he might be mistaken.

The insane delusion is deeper and more influential than the imperative conception. The former rules the patient; the latter can be, at times, controlled by him. The delusion enters into the very constitution of the patient's ego; he lives and moves and has his being in his delusions. It colors and outlines his objective world. The so-called imperative idea, on the other hand, is recognized by the patient to be a mere subjective phenomenon; annoying and persistent, it may be; yet it is possible to dispel it by rational analysis and earnest effort. Hallucinations and illusions are almost always associated with the false beliefs of the insane; hallucinations and illusions rarely, if ever, bear directly upon the imperative conceptions of the sane. Volition is enthralled by insane delusions; volition is free so far as the imperative conceptions of the sane are concerned. The suicidal and homicidal tendencies of the insane are usually the outgrowth of their delusions; the

imperative conceptions of the sane do not lead to the taking of life. In nearly all cases of homicide, committed during an epileptiform seizure, there will be discovered, as the result of diligent search, certain more or less pronounced delusions, if not actual illusions and hallucinations.

The imperative conceptions of the sane may be a forewarning of mental breakdown, but they are not necessarily indicative of existing insanity. Dean Swift, when at the height of his intellectual power, suffered from the ever-present fear that he would begin dying at the top like the trees in the fall of the year. As everybody knows his fear was all too sadly realized. Dr. Johnson was also the victim of an imperative conception. As Macaulay says, "he would conceive an unintelligible aversion to a particular alley and perform a great circuit rather than see the hateful place. He would set his heart on touching every post in the streets through which he walked. If by any chance he missed a post, he would go back a hundred yards and repair the omission." He was hypochondriacal and subject to fits of melancholy all his life. He was not insane, though decidedly neurotic. Many of his eccentricities of manner and dress were the result of his early training, his long struggle with poverty, his uncongenial environment and his indifference to petty things, so often shown by men of large minds. In speaking of his "Lives of the Poets," even Macaulay, who inclines to the view that the great lexicographer was not quite sane, says that his "remarks on life and on human nature are eminently shrewd and profound. The criticisms are often excellent, and even when grossly and provokingly unjust, well deserve to be studied. For, however erroneous they may be, they are never silly. *They are the judgments of a mind trammeled by prejudice and deficient in sensibility, but vigorous and acute.* (Italics ours.) During his last illness when death was drawing near "the ablest physicians and surgeons attended him and refused to accept fees from him. Burke parted from him with deep emotion. Windham sat much in the sick room, arranged the pillows, and sent his own servant to watch at night by the bed. Frances Burney, whom the old man had cherished with fatherly kindness, stood weeping at the door; while Langton, whose piety eminently qualified him to be an adviser and comforter at such a time, received the last pressure of his friend's hand. . . . And it is but just to say that our intimate acquaintance with what he would himself have called the anfractuosities of his intellect and of his temper, serves only to strengthen our conviction that he was both a great and a good man." All of which could scarcely have been affirmed of one who was insane!

In order to further emphasize and illustrate the difference between the imperative ideas of the sane and of the insane, I will quote from my private notes four cases, the first two of whom were sane, the last two insane.

1. This patient, an unmarried woman, past middle life, was, like Dr. Johnson, addicted to the senseless habit of repetition. Whenever she picked up an article, say a plate from the table, she would invariably turn it over half a dozen or more times to examine the bottom, before laying it down. If she passed through a door, she would open and close it a number of times before leaving it. Everything she did, she seemed to be doubtful about, and would invariably repeat a number of times before feeling satisfied. She manifested the symptom of fear, though she always denied fear. She would frequently turn half-way round, whether on the street or in the house, not systematically but occasionally, as though she had suspicions of some one following her. There were no hallucinations or illusions, and when asked why she acted thus, she would smile and declare that she did not know. She felt simply an irresistible desire to do it, an imperative conception. She had been considered odd all her life, but not in the least insane. She was devoted and affectionate, traveled and attended to her small business affairs with much skill. Perfectly normal and supposedly healthy individuals sometimes manifest this doubting state of mind, and unless great care be exercised to avoid it the habit will grow and cause much annoyance to the victim and his associates. The symptom when not the result of mere habit, reveals a slight congenital or acquired weakening of the mental forces, which may be the result of such various factors as bad discipline and education, physical exhaustion, toxæmia, and other vicious and debilitating influences.

2. This patient was a highly-educated divinity student, about thirty years of age. By means of extracts from the long "confession" which he wrote for me, I will let him explain his own acts and mental state, which he has done so vividly, merely premising that there was no neurotic heredity, no exciting causes, such as we usually find in these cases, involving the emotional and sexual life, but only the predisposing cause of severe study, with unwonted application to those branches of knowledge, such as logic and psychology, which favor much self-introspection. After making some unimportant statements in regard to his birth, parentage, previous condition of health, etc., he begins "as a child I was very sensitive, emotional, and I might add, characteristically tinged with melancholy. Sad tales, narrated in my school reading-books had a peculiar fascination for me, and I read them so frequently that I can, with a little reflection, recite many of them almost *verbatim et literatim* at the present time. Very early in life I had a taste for poetry, and was fond of thinking I would some day be a poet. At the age of thirteen or fourteen years, I had considerably developed a dreamy, poetical temperament." The development of such a temperament is not to be regarded as a sign of mental deterioration, for it may be the natural consequence of a false discipline or the result of an unsocial habit fostered by uncongenial environment due to differences of intellectual tastes. The fondness for solitude and day-dreaming, which Lombroso and his school make so much of as one of the indications of the insanity of genius, is more often the necessary result of the stupidity, ignorance, and indifference of the people among whom the genius is born. My patient clearly recognizes one of the commoner causes of this solitary, dream habit when he declares that "it may have been promoted by the fact that my parents never allowed me to associate freely with boys of my age. I have sometimes thought that here my social instincts were warped, and that perhaps here was laid the foundation of that feeling that has developed with years, viz., that I am not just like others and can't be." It is always unfortunate in such cases as these that the exaggeration and sharp definition of the ego, fostered by the earlier unsocial habits, should, as a rule, be still more increased by the higher education and its temptation to indulge in close self-analysis, which this class of individuals so ardently pursue.

Before entering college the patient was for a short time in the mercantile life, and while there enjoyed both his work and social pleasures "with little if any of the peculiar symptoms which later developed." The mercantile life being so largely materialistic, social, and competitive, it is not conducive to the cultivation of the habits of seclusion and self-analysis, and hence is well adapted to counteract the

tendencies of this and similar patients. I have often recommended such individuals to give up their studies, at least for a time, and enter the commercial world.

After entering college, the first indications of his present distressing frame of mind began to exhibit themselves. He says "at once I was overawed by the dignity of the professors and of those in authority, and I marked it as not a little strange that many of my fellow-students could meet and engage these same men with freedom and composure. And right here, let me say, was first brought to my mind a sense of *timidity when in the presence of strangers*, and especially so with my *superiors*. I never could feel easy in their presence, and was *always methodical in avoiding them*."

Note the next paragraph in this remarkably clear self-analysis. "I have ever since been engaged in study, and always stood among the leaders of my classes, ever, nevertheless, *avoiding professors* and those whom I observed to possess more than ordinary endowments. And it may be in place to state here that I have never had any *solid confidence* in my own *abilities*, being strangely prone to compare myself in this regard with others, and to force from such companions, regardless of evidence, a conclusion adverse to myself. Consequently, among those who know me familiarly, my modesty is almost proverbial. And yet, in my own mind, I am not entirely modest. I often feel that I possess superior powers, but courage to assert it is always wanting." The exaggeration of the ego is a common observation among the insane, among the neurasthenic, and among men of genius. The popular notion is that in all cases it is the expression of an inordinate and disgusting vanity. Lombroso has so far failed to distinguish one form from the other that he again makes use of this symptom to indicate the connection between genius and insanity. There is, however, a vast difference between the egotism of the mentally unsound and that of men of genius. In the former it is an unwarrantable pride in the *supposed* possession of powers which never materialize, however, into any actual or worthy production; in the latter it is a laudable satisfaction in real ability as shown by commendable work actually done. As Ruskin has pointed out, great men know that they can do certain things, and they do them. Sir Isaac Newton knew that he had the ability to work out certain problems which other men could not solve; Arnolfo knew that he could build a good dome at Florence. And yet, with all this knowledge of their own great abilities these men are filled with humility. With them their pride is first in their work and secondly in their power to accomplish that work. The insane man reveals his egotism often in identifying himself with great men, even assuming their names and manners while doing and saying things absolutely irrelevant and inconsequential. The mildly insane man, the neurasthenic, and the vain individual also mildly identifies himself with the great by imitating the eccentricities of the latter, by speaking of them in an over-familiar way, as though he and they were all of the same company, and in many other ways. With them their pride is primarily in their imaginary abilities, and secondarily in their work, if by any chance a single one of them accomplishes some petty trifle. The neurasthenic of average ability especially betrays the exaggeration of his ego by always "suspecting" that he "possesses superior powers," but in never having "the courage" (rather let us say, the real power) to assert it in a tangible and commendable form. Vanity, therefore, should be predicated only of the egotism of the mentally weak, but not of the egotism of real genius.

Let us proceed with the patient's self-examination and observe the steady growth and fixation of the imperative conceptions which he now finds so intrusive and from which he hopes to escape through medical advice. "During the last five years I have grown *suspicious* of people in general" (unwarranted vanity is always suspicious for very obvious reasons!) "feeling as it were, that I am the 'observed of all observers,' generally regarded with distrust and as one whom they wished *to avoid*, if possible. Within this period, also, I have observed that I always disliked anything light, humorous, or frivolous." Probably he did not dislike the humorous and frivolous when he was alone. With the play of light and frivolous conversation there is apt to be occasional scintillations of wit and satire of a more or less personal character, and this at times offends the neurasthenic's hypersensitiveness and *amour propre*. The patient reveals this in what immediately follows. "I have felt a growing tendency to resent any *freedom* or *liberties*, such as college boys take with each other, such as pushing, wrestling, teasing, etc. It seemed that I became *serious* in everything. It had ever been characteristic of my nature to be sociable, but something seemed to be dwarfing these faculties. . . . I imagined I was sick in one way or another; consulted a physician now and again for vague and ill-defined disorders. Insomnia annoyed me very much, and I became much dejected in my efforts to find out the precise nature of my malady, always thinking it something physical." He began to fear, about two years ago, that his mind was breaking down. "The tyranny of the thought became awful. I could not escape from it. My mind operated much like the vitascope, constantly flashing before me verses or stanzas of poetry I had read, propositions from philosophy, sentences I had written, etc., giving me no rest. . . . Prior to this period, perhaps as much as four years ago, I observed that I was beginning to stare. The eye has ever played a strong part in my disorder. I have always a dread of catching another's eye, as if in the interchange of glances was revealed the 'something wrong.' But in darkness I am entirely self-possessed and easy in any company, and even feel that I am agreeable to the company; while in the light, the eye of a child will unnerve me and urge me to get away and be alone." The eye is probably the most expressive single feature in the human countenance; hence both subjectively and objectively it always plays a great rôle in the symptomatology of the egotistic neurasthenic. "This symptom," continues the patient, "is not always the same, and while I am never entirely free of it, yet it becomes, at times, painfully acute. In this state I do not wish to see anyone, though if it cannot be avoided and something very interesting be under discussion, I forget my troubles, do not feel conscious of staring and feel as if a new man were in the place of the 'old.' But when conversation becomes dull, as it readily does, I at once fall back into my painful consciousness, if I may so call it, and the awful incubus is again upon me! I stare fearfully and want to escape, if possible. The moments are torturing; fear comes upon me, not physical is it, but rather, I suppose, moral—a fear of criticism, and I imagine the first utterance after I leave will be: 'There's something wrong with that fellow!'" The patient has attempted to diagnose his own case in the closing curious paragraph. He has named the chief symptom of his trouble "a permanent idea," but not being a student of medicine he does not recognize that he is the victim of psychical neurasthenia, sometimes called cerebrasthenia, the causes of which have been excessive study and self-analysis superimposed upon an early false training. He says

"the relations which exist between these various feelings are not entirely evident to me, though I have given thought to the question. What is *cause* and what *effect* seems difficult to answer. The only solution, however, that satisfies me is that I have *a permanent idea* that people in general have *evil* and *malevolent* designs upon me. This, it appears to me, excites that fear to which I have alluded, and from this follows the staring. For I have observed that persons of affable and deferential manners dispel this feeling, while those of the opposite character appreciably excite it. Hence I feel much more easy in the company of some than of others. But I am at a loss to know how such an idea could seat itself in my mind. Nobody ever did me any considerable injury that would give grounds for such an idea." I have quoted the patient's own words, italics included, as his description is so true of the neurasthenic state. The fear he speaks of is not the fear that sometimes springs out of delusions of insanity as in one of the following cases, prompting the patient to commit homicide; it is rather the fear of having his *amour propre* wounded, its source being in his vanity, his inordinate egotism. This distinction between the phobias associated with the imperative conceptions of the sane and the phobias associated with the delusions of the insane, should be carefully remembered. Unlike the fears of this case, which, it will be observed, are secondary to a mental hyperæsthesia and exaggeration of the ego, the fears of the two following cases, both insane, constituted the very ego itself, as it were, and entered as primary factors into the patient's mental makeup. The neurasthenic recognized his fears and could study them himself as though he were something separate and apart from them; the insane did not recognize theirs as fears, but accepted them as the logical and necessary basis for their manner of acting.

3. An unmarried man, twenty-seven years of age, with a highly neurotic heredity, was the victim of the insane delusion that he was under the control of spirits and other unseen agents. When a boy, he was struck on the side of the head. A discharge from the ear of the same side followed; and during the rest of his life there has been deafness in that ear. There has been no running from the ear for many years. Nervous troubles, without insanity, have been common in his family, especially on the paternal side. The father's relatives have all been quick-tempered and violent, and suffered much from neuralgias and headaches. One uncle used alcohol to great excess; the father contracted gonorrhœa, and had rheumatism followed by mitral insufficiency. The mother is hysterical and nervous; two sisters are highly hysterical; a third sister died of rapid pulmonary tuberculosis; while the patient himself has had many scrofulous glands removed from the neck. Two years before I saw him he was remanded to the Detention Hospital, but since he had been out he was fairly tractable, though inclined to be morose, melancholy, and obstinate. He is a skilled draughtsman, and a keen mathematician. Apparently rational, he is fond of minutiæ, and greatly given to detail work. In ordinary conversation one would never suspect him of insanity. And yet he imagines he hears voices calling him, especially at night. They trouble him at times during the day. They are usually pleasant, female voices, though sometimes they are threatening, masculine voices. They always come from a distance, even from the opposite side of the world, from above and from below. They are borne to him by means of some abstruse, unknown electrical means, for this purpose not needing any other conductor than the intervening air. Masturbation years ago was admitted. His dreams are highly erotic, and as the result of them, and of the imaginary voices, he almost nightly leaps out of bed, seizes an Indian club, poker, or other convenient article and pounds on the doors and walls, shouting to the spirits to stop calling and annoying him. He threatens injury if he can only come at them. At times he says he can see people floating before him and threatening him with personal violence. At these times all his acts are in perfect accord with these imaginary conditions. So great is his fear and delusion that he has threatened to kill even his father and mother. I sent the patient, at once, to the asylum. My purpose in referring to the case in this connection is to show how the patient's whole manner of action was determined by these delusions, which delusions, probably depending largely upon the visual and auditory hallucinations, color and even constitute the whole world of his ego. He cannot reason intelligently about these delusions, though he reasons with a kind of logical sequence within them. They are, therefore, the imperative conceptions of insanity.

4. Another young, unmarried man, twenty-seven years of age, whom I saw some time ago, declared that he was annoyed by voices calling to him during the day, but more particularly at night. He hears them more distinctly in the left than in the right ear. He identifies one of the voices as that of the "old boy" persuading him to do some wrong. He cannot describe the appearance of the "old boy" or the character of the temptation. Visual and auditory hallucinations are positively denied by the patient. He says he does not dream, and he is not troubled with lascivious thoughts. The mother of the patient says she was delirious with an attack of erysipelas when his birth took place at eight months. When seven months old, the patient had an abscess opened in the neck. Measles occurred at fourteen months of age. He had a severe fall down a long flight of steps at fifteen months; after which he ceased to talk until he was about four years of age. Epileptiform convulsions began when he was fifteen months old, finally stopping when he was eight years of age. He has had an attack of sunstroke; has always been fearful and irritable and consumed with the one idea of being a printer. There was no heredity of any importance. Many other details in my notes I will omit, as I wish to refer to the case only to illustrate the imperative conceptions of the insane, and how they determined this patient's entire mode of thinking and acting. Having strong homicidal tendencies under the delusions of these imperative conceptions, he was promptly sent to an asylum.

A young man, twenty-two years of age, referred to me by Dr. W. A. Mann, came of a markedly neurotic ancestry; was always considered very delicate, and was therefore always greatly humored. In addition to being addicted to cigarette smoking, he fell and hurt his spine and was treated for a long time for acute Bright's disease. A few days before I saw him, he had been greatly shocked and frightened by seeing a man threaten and attempt to kill a girl. He began to experience marked hallucinations of hearing, and was fearful all the time under the delusion that detectives were constantly dogging him. He declared he could hear the detectives whistling and it greatly angered him, so that he threatened to kill them whenever the opportunity presented itself. After talking quietly and rationally in my office, he suddenly began to chatter about his journalistic ventures and skill as a great war correspondent. As a matter of fact this was all a pure delusion, as he had never done any such work. He imagined that he was the greatest war correspondent in the world, that he was in the employ of all the great newspapers of

America and Europe, that he always managed to get the news first, and that his rivals knew of this and were ceaselessly trying to harass and supplant him. He volunteered to show me, if I would give him a pencil and some paper, how he wrote up the great battles then going on in South Africa. Then, suddenly becoming violent, leaping up and staring out of the window, he cried out, "But I'll get them some day. They are after me, and are trying to get at my secrets, and if they don't look out, I will kill them." The patient was admitted to the asylum.

I have omitted details in these cases, reporting them here merely to show how the patients, unlike those reported in the early part of this paper, did not and could not reason about their hallucinations and delusions, but acted logically in accordance with the dictates of their imperative conceptions or delusions. If you reason with the neurasthenic about his fixed ideas, he will recognize that they are abnormal, will smile at them himself, will ask your advice as to the best way of getting rid of them and will make an effort not to be influenced in thought or manner by them. On the other hand, if you attempt to reason with the victim of insanity in regard to his fixed ideas, even though he may be only a mild monomaniac, rational in all other things beside these ideas, he will manifest no confusion, and instead of asking you how he may get rid of them, will show a slight degree of irritability and disgust at your doubt in regard to them. Those patients who hear nocturnal voices, insist that they are real, and that they are actually heard by them, when they talk with you in the daytime during their lucid moments.

The imperative conception may involve all the faculties of the mind. It is a mistake to associate it with the imagination only, as some have tried to do. The memory, the imagination, and the intellect may individually or collectively be concerned in its production. A high degree of amnesia, such as we sometimes see in severe alcoholic intoxication or the excessive use of nicotine, will cause the victim to repeat, under a seeming compulsion, purposeless and irrelevant acts. A melody heard long ago will recur in the patient's mind with annoying persistency. Certain names, figures, problems, and incidents cling to the memory in spite of every effort to eradicate them. On the other hand, the imagination, especially under the high excitability usually given to it by general neuropaths, frequently develops ideas and conceptions that are persistent and lead to irrelevant acts. There are usually no distinct hallucinations or delusions with these impulsive conceptions. Memory and imagination are not infrequently involved together. A nervous lad, seventeen years of age, now under my care, saw his brother accidentally drowned several years ago. Now, the mere recital of a drowning in his presence throws him into a high state of excitement and awakens such distressing and vague fears that it is almost impossible to get him to leave his room. He is not melancholy, has no suicidal thoughts, and can reason most clearly in regard to the foolishness of his fears. And yet, in spite of his best efforts, he not only feels but shows that the very thought of crossing a bridge over a stream of water is horrible in the extreme. Martin Luther saw the devil and hurled an inkstand at him. This was probably an indistinct visual disturbance, the result of an overwrought imagination influenced by the common belief of the day in a personal, living devil. The early education, as well as the common beliefs of the day, should always be taken into account when differentiating insane from sane conceptions. It was only after years and years of effort that Goethe could overcome an ill-defined, superstitious dread. Like many children with a poetical temperament, he was sensitive and suffered from childish terrors. To overcome this, his somewhat stern and opinionated father used to compel him to sleep alone, and when the lad stole away from his own bed to that of his brothers, would chase him back disguised as a fantastic hobgoblin. Some of the terrors which Hoffman, the German romancer, suffered from, and on account of which he would call his wife to come and sit beside him while he wrote, were probably due to the overuse of the imagination with defective inhibition on the part of the intellect. Hoffman died of locomotor ataxia with terminal dementia. Note the different etiological foundations for the phobias and imperative conceptions of these three geniuses. They all feared, more or less distinctly, unseen agents, goblins, weird creatures. They were all the victims of imperative ideas. Luther was under a high strain, and therefore was probably neurasthenic. Indistinct illusions of sight are not uncommon in extreme nervous prostration. It was not unnatural that his illusion should assume the form of the devil in whom he believed, in harmony with the general belief of the day. This was not an insane delusion, as we usually understand it. Goethe was made the subject of his fears by a vicious training in early life. He, however, recognized their groundless character, and, by a continued, heroic effort, ultimately freed himself from them. Goethe's were not, therefore, insane fears, the result of mental aberration. Hoffman never got rid of his terrors. As the result of visual hallucinations and deep-seated psychic depression, he begged his wife to sit beside him hour after hour to scare off the goblins while he wrote. He never could be induced to laugh at or reason away his baseless fears. They constituted a part of his mental existence. He actually beheld the spirits, and always acted as if they were really present to others as well as to himself. This was an insane delusion, and unlike the preceding two, belonged to that class which Lombroso and his followers have accepted as an indication of the insanity of genius. The hallucinations of Luther and the superstitious dread of Goethe were sane conceptions, if I may be allowed the paradox, and do not lend validity to the contention of Lombroso anent the insanity of genius. Insanity is a broad and much-abused term. It should be replaced by the word psychosis, for with the former there is associated the notion of a sharp line of demarcation between mental health and mental disease, whereas all forms of mental debility, from the mildest aberration to the severest, from the slightest weakening of the patient's usual mental grasp to the most violent mania or hopeless dementia, may be comprehended under the latter. Impulsive ideas, as well as insane delusions, are to be classified as psychoses, but the former are at the beginning of the scale and easily recovered from, the latter at the end of it and generally hopeless.

The treatment for the eradication of these imperative conceptions is both physical and mental, both medicinal and disciplinary. When they are due to physical debility, organic insufficiencies, or toxic blood states, the relief of the latter will, in time, cause the disappearance of the psychic abnormalities. Every organ in the body should be sharply interrogated, and measures should be adopted to restore them to their proper functional activity. Obscure renal disease, weakened heart-action, or inefficient gastrointestinal peristalsis may lead to such a general condition of malnutrition as to affect decidedly the mental functions. The patient should be carefully studied as an organic compound. The treatment should not be instituted with the attention too closely riveted on any one organ. I have known of

the liver being blamed, and of chologogues being administered when exercise and a selected diet were all that was needed. I have seen exercise and a selected diet recommended to tone up the muscular system when assimilation was the chief element at fault. No class of cases needs a closer scrutiny or a more thoughtful therapeusis than do these. The mind, if not coextensive with the entire organism, is, nevertheless, powerfully under the influence of every part of it.

Insane delusions are, primarily, the result of a diseased cortex; imperative conceptions are the result generally of disease outside of the brain. Hence, a more thorough examination of the patient is necessary, as a rule, to discover the cause of the latter than that of the former. The cause of the latter being once discovered, the therapeutical and dietetic management, the physical treatment of the case will be obvious enough, and will involve a consideration of the entire field of internal medicine.

Medicinal treatment alone will not avail with some patients who are the victims of these troublesome phobias and impulsive ideas. The habit once formed, becomes persistent and is hard to get rid of. Note the example of Goethe cited above. In these cases disciplinary, educational, and environmental influences play a large rôle. The medical adviser must here become a character builder. He must keep in close touch with his patient, must exercise a strong personal influence over him, and must both do and say that which will tend to win him away from his psychic depression. This is a very large task, and it is at times exceedingly discouraging; but to the student of the mind and its vagaries, it is so fascinating that the difficulty of the task sinks into insignificance in comparison. To observe, analyze, and mould such a character demands a higher degree of skill than to watch, study, and control a case of typhoid fever or pneumonia. Patients of this type are not infrequently shrewder, deeper, and more intellectual than the medical consultant. While he may be fully able to suggest to them the proper medicines, food, and exercise, he too often shows the limitations of his own mental capability for healing the mind diseased. These patients call for something more than diet and medicines; they need advice frequently as to their reading, studies in art, scientific amusements, as well as the whole tenor of their intellectual lives. For instance, a precocious, highly emotional girl becomes hysterical. It is discovered that she is studying music. It will not do to tell her to give up her music absolutely; hence a selection must be made between studying Mozart and Bach, who are sedative, intellectual, and disciplinary, and Chopin, and Liszt, who are stimulating, emotional, and erratic. How can a physician obtain the best results in the treatment of such a case unless he is somewhat acquainted with the art of music? Among the great writers, Washington Irving is as different from Alexandre Dumas, or Goldsmith from Byron, as a soothing draught is different from an alcoholic stimulant. As I intimated before, one cannot tell these patients not to read at all, for the ennui that sometimes results would be worse than the disease. Therefore, it behooves the attendant to know a little—yes, a great deal—about general literature. How many physicians prepare themselves to treat and manage in this way these mentally overactive, imaginative, irritable, restless individuals? Here, more than elsewhere, do we, as a profession, too glaringly expose the one-sidedness of our training and pretensions. Our energies are too closely confined to the prescription and the scalpel.

100 State Street.

EXAMINATION OF MILK BY THE GENERAL PRACTITIONER.*

By HENRY LARNED KEITH SHAW, M.D.,
ALBANY, N. Y.

Clinical methods for the examination of the patient and his excretions are now largely employed in the daily practice of physicians. The examination of urine, sputum, blood, and stomach contents can be made in a short time, and medical students are well drilled in the technique of these methods before leaving the medical school, and can deduct correct conclusions from their examinations.

In this paper it is purposed to outline a rapid and simple method of examining either human or cow's milk. There is a very prevalent idea abroad that a milk analysis requires expert chemical skill, expensive apparatus, and much time. For these reasons the general practitioner rarely, if ever, attempts to determine the character of the milk from a mother whose baby does not thrive. As a result the child is weaned from the breast and some much advertised food is prescribed.

It is not the object of this paper to discuss the importance and value of milk examinations, but it can be said that it is impossible to feed infants scientifically or intelligently without making, or having made, milk examinations from time to time.

A practical examination for a physician must be easy of application, consume little time, require simple and inexpensive apparatus, and be accurate in order to reach reliable conclusions. The scheme I wish to present does not take much more time than a complete chemical urinalysis, and requires no more skill. No originality is claimed, for "I have gathered a bunch of other men's roses, and only the cord that binds them is my own."

Care must be taken in obtaining the sample of mother's milk to remove all the milk from the breast. The composition of the fore milk differs from the last portion withdrawn. The sample of cow's milk should be well mixed before testing.

The first step is to determine the total acidity of the milk. With cow's milk this determination is of vast importance. Milk with an acidity of over .16 per cent. should never be used for infant feeding. The limit for drinking purposes is .2 per cent., and .3 per cent. is the point of souring. There is a close and definite relation between the degree of acidity and the number of bacteria. Souring is due to lactic acid producing bacteria, and milk containing many bacteria will have a high acidity. In this way we get some idea of the cleanliness employed at the dairy, and of the care taken in the transportation and delivery of the milk. There is a very practical bearing to us as physicians, for "milk on the point of souring is very liable to produce gastric and intestinal catarrhs of an acute or chronic character in infants, children or persons with feeble digestion." The chief causes for an untimely acidity of the milk are improper feeding of the cows, dirty milk pans and rooms, unclean udders and teats, and a high temperature.

The articles required in making this test are few, and consist of an alcoholic solution of phenolphthaline, decinormal sodic hydrate solution or a saturated solution of lime water, a small glass beaker, medicine dropper, and a small glass cylinder holding 10 c.c. and graduated into tenths of 1 c.c.

Five c.c. of the milk are measured into the beaker and a couple of drops of the phenolphthaline solution added. The cylinder is then cleansed and filled

*Read at the ninety-seventh annual meeting of the Medical Society of the State of New York, January 27-29, 1903.

to the 10 c.c. mark with either alkaline solution. A small amount of the solution is taken up by the medicine dropper and added drop by drop to the milk, which is well stirred with a glass rod. When a faint pink color is obtained the excess of alkaline solution is returned to the cylinder and the amount of the alkaline solution used is readily ascertained.

The following formula is employed when the sodic hydrate solution is employed:

$$\frac{\text{c.c. alkali} \times .009}{\text{c.c. sample taken}} \times 100 = \text{total acidity.}$$

For example, if it takes .8 of 1 c.c. to neutralize 5 c.c. of milk the equation would read:

$$\frac{.8 \times .009}{5} \times 100 = .145 \text{ per cent.}$$

A saturated solution of lime water is approximately a one-twentieth normal solution, and when this is used the formula would read as follows:

$$\frac{\text{c.c. alkali} \times .0045}{\text{c.c. sample of milk}} \times 100 = \text{total acidity.}$$

A somewhat simpler but not so accurate a method is to use the Farrington alkaline tablets. These tablets consist of a definite quantity of alkali combined with coloring matter. These tablets keep much better than the standard solutions, require no apparatus and are very cheap. The test is made as follows: One tablet is dissolved in a half ounce of water. Two c.c. of this solution are added to a like quantity of milk. If the resulting mixture, after shaking, is pink, the milk contains less than two tenths of 1 per cent. acidity. If the milk remains white it contains more than two-tenths of 1 per cent. and is too sour to use, even though it smells and tastes sweet. Other combinations can be tried, such as adding 1 c.c. of the solution to 2 c.c. of milk. A resulting pink color would indicate an acidity of less than one-tenth of 1 per cent.

A standard decinormal alkaline solution can be made by dissolving twelve of these tablets in 50 c.c. of water. When this is used for the titration it is unnecessary to add phenolphthalein to the milk.

The specific gravity of the milk is next ascertained. For this purpose there are two types of lactometers. The New York Board of Health lactometer does not give the specific gravity of the milk directly, but has a scale divided into 120 equal parts, the mark 100 being placed at the point to which the lactometer sinks when lowered into milk of a specific gravity of 1.029 at 60° F. This lactometer requires a large amount of milk and certain calculations to convert the reading into the specific gravity.

The other type of lactometer is the Quevenne, which has the same scale as the ordinary urinometer, and registers the specific gravity directly. These lactometers are standardized at 60° F., and as the correct reading depends on the temperature of the milk these lactometers contain thermometers. Knowing the lactometer reading at a certain temperature, the specific gravity can be easily ascertained. A simple rule is to add .1 to lactometer reading for each degree above 60° F. and to subtract .1 for each degree below 60° F. The corrected reading can be found at a glance by using the sliding milk rule, which will be described later.

As the Quevenne lactometers on the market which contained thermometers were large and required a large quantity of milk, I had one made with a scale from 1020 to 1050, which only requires a little over half an ounce of milk to obtain a reading. This lactometer contains a thermometer, so that the temperature of the milk can be ascertained at the same time.

The reading must be made with care, for important information is obtained from it. The specific gravity of mother's milk averages 1030, and it is lowered by an increase of fat and raised by a high percentage of proteids. If the specific gravity of cow's milk is less than the normal (1029 at 60° F.) one of two things may be assumed. Either the milk contains an unusual amount of cream or the milk has been watered. If, on the other hand, the specific gravity is higher than normal and the percentage of fat is low, it is fair to assume that the milk has been skimmed. The most important use of the lactometer is to determine the percentage of solids in the milk and formulæ for this purpose will be given in another part of this paper.

The percentage of fat may be determined by many methods. We cannot at this time enter into a discussion of the relative merits of these methods. The principle of most of these is similar, and consists of dissolving out the solids not fat of the milk by means of various chemicals, and the fat either measured as such in a narrow graduated tube or brought into solution with ether, gasoline, etc., and weighed on evaporation of the solvent. The test suggested by Professor Babcock of Wisconsin, and known as the Babcock test, is the simplest and most accurate, and has replaced most of the older methods. No expert chemical knowledge is required and only one chemical is used. The accuracy of this test is such that several States employ it for their official examinations, and it is in very general use throughout the United States. The manipulations are few and easily learned, while the apparatus is

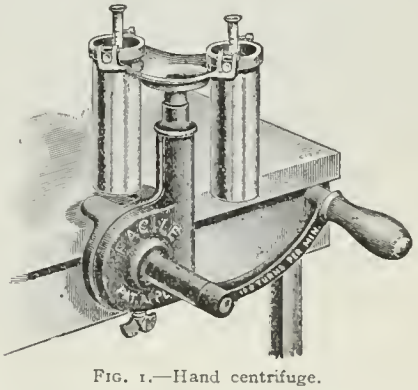

Fig. 1.—Hand centrifuge.

very cheap. The glassware consists of test bottles, a milk pipette, and an acid measure. The test bottles have a capacity of about 50 c.c. and are made of heavy, well-annealed glass. The neck of the test bottle on which the scale is sketched is three inches long, and is graduated from one to five or one to ten per cent., and small divisions make possible the estimation of the fat into tenths of one c.c. with perfect ease. Special bottles are used for testing cream and skim milk.

The Babcock tester is a centrifugal machine run by hand, steam or motor power. The machines on the market are all large and cumbersome, and are not practical for the physician's use. At my suggestion one of the large dairy supply houses, D. H. Burrell & Co. of Little Falls, N. Y., made a small hand centrifuge which is thoroughly practical, requires the regulation size Babcock test bottles, and takes up very little room in the physician's laboratory. In order to make this centrifuge of greater value to physicians, special sediment tubes are supplied, so that the machine can be used for urinary or other work. These tubes have a detachable tip, which is kept in place by cohesion of two

ground-glass surfaces. The sediment from a large quantity of urine can be collected in the small cap, which is of great value in the detection of typhoid and tubercle bacilli. These caps can be thoroughly cleansed, and the sediment easily collected and removed for microscopical work.

Fig. 2.—Test bottle. (½ size.)

Fig. 3.—Sediment tube. (½ size.)

The Babcock test is made as follows: Seventeen and six tenths c.c. of the milk are drawn into the milk pipette and allowed to run into one of the test bottles. Seventeen and a half c.c. of clean sulphuric acid with a specific gravity of 1.082 are measured in the acid measure and slowly run into the test bottle.

The milk and acid are thoroughly mixed in the test bottle by a rotary motion, placed in the centrifuge and whirled for four minutes. Boiling water is then added by means of the pipette until the lower part of the column of fat comes within the scale on the neck of the test bottle. A second whirling for one minute completes the separation of the fat. The test comes out clearer and nicer, and the fat is kept more limpid if boiling water is put in the cups which surround the bottles. The fat thus obtained should form a clear, yellowish liquid quite distinctly separated from the acid solution. The bottles must be kept warm until the readings are made. The fat is measured from the lower line of demarcation between the fat and the water, to the top of the meniscus of the upper line. The liability of error in reading is rendered less by using an ordinary pair of dividers. After the extent of the fat column is obtained the lower point of the dividers is placed at the zero mark of the scale and the percentage of fat read at the upper point. The normal variations in both mother's and cow's milk are from 3 to 5 per cent.

The test requires an ordinary amount of care, and a few cautions are necessary. The milk to be tested should be thoroughly stirred before the sample is taken. In order to balance the machine two tests must be made at a time, and if sufficient milk is obtainable it is a good plan to make a control test. The speed of the tester must be regular, and in order to obtain the clearest readings the milk and acid should be about 70° F. before mixing.

The mixing of the milk and acid must be done with care. When once begun the mixing should be continued until completed, for a partial, or interrupted mixing will often cause some black material to separate with the fat and obscure the reading. This will also occur if the acid is too strong. The water added in order to bring the fat into the neck of the bottles should be soft, or else the carbonic acid gas liberated from hard water by the sulphuric acid produces a layer of foam on the fat and renders the reading more difficult.

The percentage of sugar is almost constant in both human and cow's milk, and it is not necessary to estimate the amount of sugar in an ordinary routine examination. Lactose will reduce copper salts, and the percentage of sugar present can be ascertained by the well-known Fehling quantitative test. Lactose will not ferment with yeast, so the fermentation tubes cannot be employed. The average percentage of sugar in cow's milk is 4.5 per cent., and in mother's milk it is 6.5 per cent.

The total solids of the milk can be determined from the data already procured, namely, the corrected specific gravity and the percentage of fat. Under the term "solids not fat" are included the nitrogenous matter, milk, sugar, and mineral salts. These ingredients require complex chemical methods for their determination, but the ratio of these three constituents is rarely altered, so that it is unnecessary, save in exceptional cases, to make a minute chemical examination.

A number of chemists have derived formulæ for the calculation of milk solids, and in recent years some of these have been greatly simplified. The Babcock formula has been found to be accurate and it is extremely simple. It consists of dividing the specific gravity of the milk by four, and adding to this one-fifth of the per cent. of fat. For instance, the specific gravity of a specimen of milk is 1030.8 and the fat 4 per cent. One fourth of the specific gravity is 7.7 and one-fifth of the percentage of fat is .8, so by the rule the total solids not fat would be 8.5. Adding the percentage of fat we get 12.5 as the total solids.

The formula constructed by Richmond is:

Total solids = .25 Spec. Grav. + 1.2 Fat + .14.

Using the same figures as in the Babcock calculation we would get

Total solids = .25 (1030.8) + (1.2) 4. + 14.

or

Total solids = 12.6.

To further simplify this calculation Richmond has devised a sliding milk rule based on his formula. Both the corrected lactometer reading and the amount of total solids can be obtained at a glance, and it does away with the use of mathematics. This rule has a movable slide in the center of its upper surface. On this slide are two scales, one

Fig. 4.—Sliding milk rule.

representing the specific gravity and the other the lactometer reading. On one side of the stationary portion a scale is placed indicating the total solids, 1 per cent. of total solids equals one inch and is divided into tenths. On the upper portion of the other side the fat is shown from 1 to 6 per cent. with each per cent. divided into tenths. On the lower portion of the same side a temperature scale is marked from 32° to 80° F, with an arrow opposite the 60° F. mark. The rule is operated as follows: The lactometer reading and temperature of the milk have been obtained. Set the rule with the lactometer reading that has been observed, opposite the arrow at the 60° F. mark. For the true lactometer reading or specific gravity notice the point on the movable part of the scale opposite the temperature at which

the milk stood. For example, if the lactometer reading was 30 and the temperature of the milk 75° F., you would set the lactometer reading –30– on the 60° F. temperature line, and it would be seen that the 75° line corresponds with 32 on the lactometer scale, which is the correct lactometer reading.

The percentage of fat in the milk will have already been determined. The movable portion of the rule is adjusted so that the arrow points at the percentage of fat on the scale. With the scale thus adjusted the line indicating the specific gravity or corrected lactometer reading is placed against the required percentage of total solids in the milk. Suppose, for instance, the fat is 3½ per cent., the slide would be moved so that the arrow is opposite the 3½ mark. The specific gravity was found to be 32. Opposite 32 will be found 12.4, which would be the required total solids in the milk.

The amount of the proteids can be obtained approximately by subtracting the percentage of fat, sugar, and salts from the total solids. The percentage of sugar in mother's milk averages 6.5 per cent. and rarely varies except in a small range. The average amount of the salts in mother's milk is two tenths of one per cent. In cow's milk these figures are different. The sugar averages 4.5 per cent., and the salts seven-tenths of 1 per cent.

For example, the total solids in a specimen of cow's milk amount to 12.4 per cent. and the percentage of fat is 3½, the solids not fat would be 8.9. Subtract 5.3, the sum of the sugar and salt percentage, and you would get 3.6, the amount of proteids.

While this is a rough method and throws all the error on the proteids, it gives us valuable information, which is reliable enough for ordinary modifications of milk.

It is sometimes desirable to ascertain if preservatives have been added to the milk. The most common one now in use is formaldehyde. If a violet ring is seen at the junction of the sulphuric acid and milk in the Babcock test bottle, formaldehyde may be present, although other conditions may cause it. This is the Hehner test, and is said to be very delicate. The ring will not form if the percentage of formaldehyde is over .05 of 1 per cent. The phloroglucin test is more reliable. One gram of phloroglucin is dissolved in 100 c.c. of distilled water. Ten c.c. of the suspected milk are put in a test tube and 5 c.c. of the phloroglucin solution added. One c.c. of liquor potassæ (U.S.P.) is added, and a pink color develops at once if formaldehyde is present.

The detection of other preservatives requires special skill and takes some time. Their presence, however, must be strongly suspected if the milk remains sweet to taste and smell when the amount of acidity registers three-tenths of one per cent. or over.

A Floating Sanatorium.—The Berlin correspondent of the *Daily Chronicle* states that steps are being taken by several physicians and associations to test the value of sea-air on patients suffering from consumption. Ordinary steamers, owing to the noise, unpleasant smells, and want of proper accommodation, are unsuitable. It is, therefore, proposed to build a large floating sanatorium, with roomy, open-air wards and medical supervision, and a complete equipment for scientifically testing the effects of sea-air on consumptives. After careful inquiry it has been decided that the cruising ground for the new ship will be the northeastern Atlantic, in the neighborhood of the Canary Islands. Should success attend the effort, further floating sanatoria will be built. The voyages will last about six weeks.—*British Medical Journal.*

Clinical Department.

REPORT OF A CASE OF ALMOST FATAL POISONING BY SIX GRAINS OF QUININE.

By LEWIS A. CONNER, M.D.,
NEW YORK.
ATTENDING PHYSICIAN TO THE HUDSON STREET HOSPITAL.

That small doses of quinine, in persons with especial susceptibility to the drug, may produce unpleasant, and often violent, symptoms is sufficiently well known to call for no especial comment. That such doses may seriously threaten life or even cause death, however, is much less generally understood, and is worthy, perhaps, of some emphasis in view of the unrestricted and sometimes reckless use of the drug.

A healthy man, twenty-seven years old, of medium height and slender build, was brought to the Hudson Street Hospital on the afternoon of May 11 last, in a condition of collapse. Less than an hour before he had applied to an apothecary for medicine for a "cold," and had been given five pills said to contain quinine. He had taken two pills at once, and about fifteen minutes later had noticed a burning of the skin and fluttering of the heart. To these symptoms were soon added vertigo, faintness, tachycardia, and great weakness. These symptoms had so rapidly grown worse that he had been hurried to the hospital.

When seen by the acting house physician, Dr. Beckwith, the man was conscious and complained of some abdominal pain and of intense weakness. His face was pale and was covered with cold sweat, his respirations shallow, and no pulse whatever could be felt in the radial arteries.

On listening over the præcordium, faint heart-beats, too rapid to be counted, could be heard. The patient was given vigorous stimulation subcutaneously, together with external heat, and half an hour later the radial pulse could be felt, although still very feeble. The count at this time showed 180 beats to the minute. The burning and itching of the skin, which had been noticed early, gradually increased, and, about an hour after admission, there appeared over trunk, extremities, and face a diffuse scarlatiniform rash with much swelling of the skin, especially about the face. At this time the temperature was 100° F. Under very active stimulation the patient's general condition improved steadily, although the swelling, heat, and itching of the skin caused great discomfort and restlessness. On the following morning the eruption had well-nigh disappeared, and the patient, although still very weak, insisted upon going home. Two days later he was seen again. The pulse was normal in rate and of fair force, but was somewhat irregular, and occasionally intermittent. The patient still felt very weak, but was able to be about. There was still some unpleasant itching of the skin. It is interesting to note that at no time during the attack was there either ringing of the ears or deafness.

The remaining three pills proved, on analysis, to contain each three grains of quinine sulphate. These symptoms had, therefore, been produced by six grains of the drug.

The patient volunteered the information that there existed in his family a distinct idiosyncrasy toward quinine. One sister had twice been violently poisoned by the drug and had shown symptoms similar to his own. A brother had also shown the same susceptibility. On the other hand, a second sister and his parents had never displayed any such peculiarity. He himself, some years

before, had had some disagreeable symptoms after taking quinine, but they had been mild as compared with those of the present attack, and had not made much impression upon him.

The extreme cardiac depression seen in this case, which, for a short time, was such that death seemed imminent, is the feature which chiefly distinguishes it from the many other cases in which marked susceptibility to the drug is shown. The rash, the itching and burning of the skin, and the vertigo are not uncommon symptoms, and have sometimes been produced by doses smaller than that taken in this case. Such an effect upon the heart, however, seems very rare among the published cases of poisoning by small or moderate doses of quinine. Wood[1] speaks of a case in which two grains administered by the mouth produced a furious general urticaria and cardiac depression of the most alarming character. Upshur[2] saw, in the case of a susceptible woman, thirty grains, administered in the course of sixteen hours, produce intense nausea, diarrhœa, abdominal pain, and a very feeble pulse; and saw, in the same individual, one year later, eight grains produce similar symptoms with a "thready pulse."

Husemann,[3] in 1888, collected four cases of fatal poisoning by quinine, but in all of them the amounts were relatively large. One was that of a French soldier who died after taking 12 grams (3 drachms) of quinine in the course of four hours. The other three cases occurred in children. A child of ten years died half an hour after taking between 5 and 10 grams (75 and 150 grains) of chinoidin; another child of three and a half years died in one and a half hours from less than three grams (45 grains) of quinine, and in a child of two years between 16 and 20 grains of quinine proved fatal in two and a half hours.

The most noteworthy case found is that reported by Micciché[4] in 1894: A girl of thirteen years, suffering from a severe form of malaria was given ½ gram (about 8 grains) of quinine hydrochlorate subcutaneously. Within fifteen minutes there developed severe abdominal pain and vomiting. Following this there were prostration, a small, frequent pulse, high fever, great nervous depression, and later stupor, jaundice, hæmaturia, and anuria, with death from uræmia on the seventh day. The autopsy showed marked swelling of the liver and spleen, swelling and fatty degeneration of the kidneys, and evidences of great destruction of red cells. The girl had previously shown great susceptibility to quinine, and each administration of it had been followed by vomiting, fever, and hæmaturia. The possibility that the symptoms and fatal ending in this case may have depended upon the malarial infection rather than the quinine is not discussed by the writer.

REDUCTION OF INTUSSUSCEPTION.

By DAVID J. MINCHIN, M.B.,
BERLIN, ONTARIO.

The following method of reducing an intussusception has proved successful in my hands a short time ago, in a case occurring in a child of eight months. The child was seen within four or five hours after the occurrence of the trouble, and, the nature of the case being explained to the parents, they positively refused their consent to abdominal section. The child was then inverted and the colon filled with hot water by means of a rubber bulb syringe, resembling a Politzer inflation-bag, and having a capacity of about four ounces. It was found possible to do this by pressing the syringe firmly into the anus during the child's efforts to expel the water, and then refilling the bulb when the paroxysm of straining passed over. Then, while manipulating the tumor through the abdominal wall with the left hand, the bulb was alternately compressed and relaxed, in much the same way as a plumber uses his suction bulb in clearing out a stopped-up sink pipe, and, after a little gentle manipulation in this manner, the tumor was felt to disappear under the fingers. This was followed by immediate relief of the urgent symptoms, although occasional vomiting and some pain persisted for a few hours longer, but the vomited matter was no longer offensive in character. The advantages of this procedure over the application of hydrostatic pressure by means of a fountain syringe are, the greater control which the operator has over the amount of force applied, and the benefit of an intermittent, rather than a continuous, pressure.

DEATH OF A FŒTUS FOLLOWING AN INJECTION OF DIPHTHERIA ANTITOXIN INTO THE MOTHER.

By E. R HOUGHTON, A.M., M.D.,
NEW YORK.

A question, to which as yet I have been unable to obtain an answer, has arisen in my practice. What is the effect of antitoxin on the child of a pregnant woman? My case was as follows: Mrs. A. engaged me for her confinement when she was eight months pregnant. I examined and measured her. It was to be her second child, and everything seemed normal. The fetal heartbeat was 165. In two weeks I examined her again, and found the child very vigorous and heart strong and the sound loud. A day or so later she visited a friend. While there, a doctor came in and informed my patient that there was diphtheria in the room and she must take antitoxin to render her immune. She objected and wished to consult her physician, but her objections were overruled and she submitted to the injection. At once she felt faint and very cold, but after a few moments rallied and went home. The outside air revived her. She noticed that afternoon and evening that there were no fetal movements. She sent for me. On examination, I found no fetal heart, no movements, and discovered that the child had changed from a head to a breech position. The child was freely movable, but did not respond in any way.

I saw the woman several times before satisfying myself that the child was dead. The woman was confined two weeks later, at term. The child was born dead, and showed that it had been dead some time, the skin being macerated and the placenta very friable. The confinement occurred two weeks after the injection of antitoxin. The woman did nothing to cause the calamity, and it seems improbable that there was any internal cause of death, as she had previously carried and given birth to a normal full-term child. The question is, did antitoxin affect the child or did the shock of the exposure, and the antitoxin injection cause a subplacental hemorrhage and subsequent death of the fœtus?

New York, April 4, 1903.

THE SCIENTIFIC BASIS OF "CHANGE OF AIR."

WITH a view to rendering our ideas more precise, MM. Albert Robin and Maurice Binet present, in a pamphlet entitled "Variations des Échanges respiratoires" (Grenoble, 1902), some interesting and instructive facts bearing upon the complex condition generally designated "change of air." The influences on respiration of diminished barometric pressure, light, heat, and cold, are carefully studied.

In elevated regions the barometric depression immediately slows the respiratory changes, which, however, after a period of adaptation, return to, and even sometimes surpass, the normal rate; this return, in spite of the smaller proportion of O in the atmosphere being accompanied by a more active pulmonary ventilation and a more rapid mobilization of the red corpuscles. Through greater ozonization of the air, the gaseous changes are stimulated. The greater intensity of light increases these changes, the stimulation being relatively moderated by the prominence of the ultra-violet rays. The lowering of the temperature, and the sudden variations which it undergoes, are also elements which stimulate the respiratory changes. The overactivity of the digestive functions, and the greater globular richness of the blood, concur in bringing about more active cellular life. Mountain sickness results from a diminution in the O fixed by the blood, and from the rapid consumption of that O, but also from defect of adaptation of the organism, either from causes due to itself (less rapid mobilization and deficient increase of the red corpuscles, deficient increase in pulmonary ventilation, etc.); or by a less regular intervention of some of the accelerating atmospheric conditions (light, ozonization, etc.).

Respecting the effect of temperature, cold accelerates, heat moderates, the gaseous changes. Breathed, hot and dry air sometimes increases, sometimes diminishes, the respiratory combustion. Hot and moist air stimulates it. Cold air in the majority of cases restricts it. Chilling of the naked skin by air or by the cold bath, increases the respiratory changes if sufficiently prolonged, a duration of one minute being without effect. An elevated, humid temperature, operating during a half hour, moderates the changes. A sojourn of forty minutes in a dry hot room at 56° C. moderates the changes, while a sojourn of fifteen minutes at 78° C. augments them. The changes are more actively influenced by a succession of different temperatures than by a constant temperature of the same duration, and the effect produced is in the direction of the action of the agent which predominates. In repose, cold augments the changes, dry air up to 55° C. diminishes, but at 75° C. it accentuates them. Abrupt variations increase greatly the activity of temperature upon the gaseous changes.

From the therapeutic standpoint, a mountainous climate which is in general stimulant to the respiratory changes, suits all patients in whom those changes are diminished, *e.g.* arthritics, most dyspeptics, the group of chlorotics and anæmics, and most neurasthenics. Consequently, it is necessary to examine the respiratory chemism before deciding on mountain cure. As altitude does not always influence the respiratory changes in the same direction in different subjects, after a suitable sojourn in the mountains the actual changes in a given patient should be determined. In tuberculous patients the examination should be made after a week, so that those in which the changes have undergone acceleration can return home. Mountains agree with the tuberculous with normal or retarded changes, and with tuberculous arthritics. In the much more numerous phthisical, with accelerated changes, the excitant effects of altitude on the changes are compensated by the greater purity of the air, the better hygiene, increase of appetite, and improvement of digestion. The increase in the changes can be avoided by shunning cold, abrupt variations of temperature, too brilliant sunlight, wind, etc. Cold climates where the patient breathes cold air, suits the phthisical, provided the cutaneous surface is maintained at a good medium temperature and protected against chilling. Hot, moist climates augment the respiratory changes and should be forbidden to the phthisical. The action of hot, dry climates is irregular, sometimes increasing, sometimes diminishing, the respiratory changes; for which reason, before sending a phthisical patient to such a climate, he should be examined with reference to the effect upon him of breathing dry, hot air, and the journey forbidden if the changes are augmented. Climates subject to great variations of temperature should be interdicted to the phthisical. The only hydrotherapy warranted in phthisical subjects is cold douches at very short duration, or alternating douches with predominance of the hot jet. The complete Turkish bath, stimulating the respiratory changes, is indicated when needed, as in arthritics, but is contraindicated in the phthisical. Fever and advanced lesions in the phthisical absolutely contraindicate mountain climates.

A BRITISH SYMPOSIUM ON THE ALCOHOL QUESTION.

THE London *Practitioner* some time ago contained nine papers on this subject. Dr. James Edmunds, Consulting Physician to the United Kingdom Temperance and General Provident Institution, analyzes the results of insuring in separate sections, total abstainers and drinkers, during the period 1866–1901. Calculating the expectancy alike for both classes in the Temperance Section, out of an expectancy of 8,838 deaths, 6,300 (71.2%) occurred; while in the drinkers' section, out of an expectancy of 11,727 deaths, 11,241 (95.8%) oc-

curred. The London Grand Division, Sons of Temperance, had, during the period 1896–1900, 8,686 insured against sickness, and 10,350 against disease. With an expectancy of 49,052 weeks' sickness, one of 39,600 occurred, and out of an expectancy of 397 deaths, one of 220 occurred. Recently the Division had an actuarial surplus of £21,623, after ample provision for all liabilities. The mortality for occupied males in England and Wales, from 1890 to 1892, having been on a general average 953, and for those in selected healthy localities 679, that for clergymen was 533; for gardeners, 553; grocers, 664; malsters, 884; brewers, 1,427; innkeepers, etc., 1,642; and for inn and hotel servants, 1,725. For 19 years at the Temperance Hospital, Dr. Edmunds never prescribed alcohol, and the mortality was low, and in enteric fever very favorable. Of 129 consecutive in-door operations, only three patients died, 2 after large ovariotomies in malignant disease, 1 after gangrene to the knee with atheroma, heart disease, and chronic bronchitis. No operation was shirked.

Dr. J. J. Ridge quotes the official figures of expenditures in the United Kingdom for liquors yearly from 1801 to 1900, which show an increase from £36,095,444 (£2, 4 sh., 4½d. per head) to £160,191,718 (£3, 18 sh., 8d.) in 1900, but he thinks the real amount £25,000,000 to £30,000,000 more per year. The Collective Committee of the British Medical Association, in 1887, investigated the drinking habits of 4,222 men who had died between twenty-five and sixty-five, during the three years previous; 40% were said to have been "temperate," and 55% to have been more or less intemperate; and the latter were regarded as having reduced their longevity "roughly in proportion to their indulgence." The great improvement in the mortality of the young during the latter half of the nineteenth century, is not shared by men over 35. This is not due (for reasons given by the author) to the modern increased preservation of weaklings, but is attributed to the habits (especially the drinking habits) of men. Even in the eighteenth century a few physicians inculcated total abstinence; in 1839, a number of the most eminent physicians and surgeons signed a declaration favoring total abstinence; and in 1847 another was signed by some 2,000; in 1874 the London Temperance Hospital was opened; and following the Cantor Lectures of Sir B. W. Richardson, in 1876, the British Medical Temperance Association was formed with 30 to 40 members, but which now numbers 530 members, with nearly 500 abstinent affiliated students. At the Temperance Hospital, 19,209 patients have been treated; alcohol has been given to but 52 patients, 33 of whom died (evidently, however, because alcohol was given only in desperate cases). Dr. Francis Vacher shows from the Registrar-General's figures for England and Wales for 1881–1900, that 20,705 deaths occurred from chronic alcoholism, 8,250 from delirium tremens, and 72,260 from cirrhosis of the liver. The rate per million of the population has risen from, for chronic alcoholism, 33 to 95; for delirium tremens, 14 to 18; and for cirrhosis of the liver, 116 to 144; and for the total, 163 to 257. For males, the increase per million males living has been: for chronic alcoholism, 39 to 101; for delirium tremens, 25 to 31; and for cirrhosis of the liver, 134 to 162. For females, per million females living, the increase has been: for chronic alcoholism, 26 to 89; for delirium tremens, 3 to 6; from cirrhosis of the liver, 99 to 107; and the total, 128 to 222. The total deaths by ages are shown in the table:

UNDER	5	5	10	15	20	25	35	45	55	65	75	85
Chronic Alco'sm	..	..	...	31	398	4342	9009	8607	5150	1902	255	11
Delirium Trem's	..	..	...	8	192	2163	3100	1836	725	194	32	..
Cirrhosis of liver	56	89	113	95	236	3744	12568	20319	20124	12129	2580	107

A table is given showing that these diseases are markedly more prevalent in the suburban centers.

Sir W. H. Broadbent says that alcohol can render decided service in tuberculosis. In debility it should invariably be given with meals, and the measure of its value is the amount of increase of appetite. In fevers it should be withheld as long as possible; its indication is not muscular (much less subjective) weakness, but frequent pulse of low tension, with dicrotism or anacrotism, and under its use the pulse should become slower, more sustained, and less dicrotic. In pyrexia the vinous odor should disappear rapidly from the breath; if it persist, or the drinkers' foul after odor is present, alcohol should be withdrawn or reduced. Unless given too early or too rapidly pushed, 3 ounces per day will very rarely need to be exceeded, and even in pneumonia, 3 to 4 ounces is a very large amount.

Renal disease and gastric irritation contraindicate alcohol; in weaknesses of childhood it is valueless; in anæmia and chlorosis it is of very doubtful advantage; its most treacherous employment is for subjective weaknesses (even with weak pulse) and depressions.

Dr. Pierce Gould believes that in infections alcohol merely hastens exhaustion; in exhausting discharges it does harm; generally, too, in cancer; and in shock it is inferior to other remedies, but a single dose, well diluted and perhaps divided, is of use in tiding over an acute emergency. Dr. Samuel Wilks thinks alcohol a "most valuable remedy"; he has gotten practical value from classing it as a sedative rather than as a stimulant; some physicians still use it too indiscriminately, but he has never seen a habit result from its medicinal use. Sir Henry Thompson's personal experience has led him to total abstinence, six months' abstinence having resulted in the disappearance of stiffness and pains in the shoulders and back, and most of his intractable hemicrania, which later disappeared "after ceasing flesh diet, for which I substituted fish and birds;" a return to alcohol in old age was found "unquestionably injurious." Dr. G. Sims Woodhead asserts, among other things, that small amounts of alcohol destroy the healthy equilibrium of cells; it has so strong an affinity for oxygen as to postpone normal oxidation, set up abnormal metabolism, increase elimination of nitrogen, and cause fatty degeneration; it can act as an adjuvant to bacterial toxins, and to waste products, and hamper the elimination of the last; it decreases resistive power and causes diseases to run a severer course; and it is a powerful predisposer to phthisis. At college, abstainers are superiors in atletics.

Dr. J. Milne Bramwell has treated 76 dipsomaniacs and chronic alcoholics, mostly *dernier ressort* cases, hypnotically; 17 males and 11 females abstained totally to last report, 1 for 10 years, the average duration being 3 years; average age, 40; average treatments, 30. Twenty-six males and 10 females were improved, 1 abstaining 8 years, relapsing, and then abstaining 6 months; a considerable proportion improving markedly; several former habitual drunkards being now engaged in useful work and drinking rarely; average age, 39; average treatments, 32; average time since treatment, 3⅛ years. Treatment failed entirely in 10 males and 2 females; average age, 43; average treatments.

EDUCATIONAL UNIFICATION.

Until 1895 there were two distinct educational departments in New York State. The Department of Public Instruction consists of a Superintendent, elected by the Legislature every third year, two deputies, various examiners, field inspectors, a clerical force, and over one hundred commissioners superintending localities. The function of this department is to inspect and supervise all public schools known as grade schools (*i. e.* all schools under the grade of high schools). The Regents of the University of the State of New York are a constitutional body of twenty-three members (four of these are *ex-officio*, being State officers) who are elected to serve for life, by the State Legislature. Their function is to inspect and supervise the high schools, academies, and colleges of the State, control admission to professional schools, and regulate the practice of most of the learned callings. In 1895 a law was enacted which gave the Department of Public Instruction direct power to supervise high school courses in connection with the regulation of training-school classes. This unusual legislation, whereby access of a supervisory nature was made possible to the Department of Public Instruction in institutions where heretofore it was conceded that the Regents alone had advisory and corrective powers, seems to have whetted the appetite of the department officials; from year to year farther inroads have been attempted, and barely a legislative session has opened since 1895 which has not seen added attempts at encroachments on the Regents' domain. The last open attempt of this kind occurred early in the present legislative session in the guise of the "Merritt" bill, which was fathered by the Department of Public Instruction. This proposed law, based on the theory that a child residing in a school district in which there was no high school, and desirous of attending such an institution, should have his or her tuition paid by the State, and not as now by the parent, was concededly right in principle, but contained a proviso that these moneys, appropriated by the State, should be administered by the Department and *not* by the Regents.

These continuous attacks have finally roused the true friends of education to activity, and for the first time in their history the Regents have taken up the cudgel of aggression, and with an appeal to the public and to the Legislature, their part of the issue has been launched in the form of the Stevens bill. The latter is a simple yet comprehensive measure. It provides for the practical transfer of the Department of Public Instruction to Regents' control, the Regents to elect the Superintendent and to supervise the department in its entirety. Thus, all State education would be centralized, and under one responsible and constitutional head; one system would prevail from Kindergarten to University; dual inspection would cease; politics would play no part (as it necessarily must now) in the selection or retention of any educational official from Superintendent of a department to page boy in a library, and the superior standing held by the Regents in the educational world in all matters pertaining to secondary and professional education would, doubtless, be imparted to grade work, thus making the Empire State *facile princeps* in *every* department of education. The arguments against this consummation are trivial where they are not ridiculous. "The Regents, when elected, were not chosen for such added duties." Surely not! but being constitutional officials it is specifically stated that the Legislature may add to or subtract from their functions and prerogatives. "They are elected for life, and life officials are repugnant to our American ideas!" Not so! United States Supreme Court judges are elected for life, and who would alter this arrangement? "Being elected for life they are beholden to no one, and might wish to continue service when decrepit and useless." The power that created can unmake, but where is the likelihood of any Regent proving recreant when for over one hundred years none yet has violated his trust? "An Episcopalian bishop and a Catholic priest are on the Regents' Board—sects should not be represented lest the introduction of religion tend to differences. State and church should be separated!" Fudge! These men, as all other Regents, are responsible to the State for their official acts, and the first step in the direction of favoritism for any sect or antagonism against any creed would be met by such a storm of protest as to overwhelm them and stifle all attempts at repetition. If all these and other alleged arguments were to be merged and a composite made, it would be found to read "We politicians would be robbed of a portion of political pabulum, which we cannot well spare, therefore let things go as they are." The medical profession seems to be united in its attitude on this question, and is in favor of Regents' control. We realize the immense advantage which has been ours by reason of coöperation with and supervision by the Regents. Twelve years has worked a marvellously beneficent change in the status of medicine and allied professions in the State of New York, and by virtue of example elsewhere in the United States. The change dates from the law of 1890, which placed the profession of medicine as the charge of the Regents—and well have they cared for their child! Ever since its first issue, the Medical Record has stood for the best in medicine, and for the highest preliminary academic requirements for those embarking on professional careers. In keeping with that same spirit we now urge the New York State Legislature to pass the Stevens bill and thus forever divorce education and politics in the State.

Manhattan State Hospital.—Dr. L. Pierce Clark has been appointed Consulting Neurologist to the Manhattan State Hospital, Central Islip, by the New York State Commissioner in Lunacy.

Immunizing of Bacteria.

In the *Wiener klinische Wochenschrift* for January 29, 1903, Dr. Friedrich Wechsberg gives a preliminary note on his exceedingly interesting experiments upon immunizing of bacteria. Starting from the side-chain theory of Ehrlich, he reasoned that if antitoxins are, so to speak, interlocking molecules with toxins, and higher organisms are in presence of toxins capable of developing antitoxins, it is to be expected that in the presence of antitoxins bacteria might be able to develop, as a means of self-protection, an increased amount of toxin. So that whereas all previous investigations have concerned themselves with the ability of an organism to meet toxin with antitoxin, Wechsberg addressed himself to the reverse problem. Experiment showed that diphtheria bacilli from one and the same colony, bred upon pure bouillon, and upon bouillon plus a definite amount of diphtheria antitoxin, showed degrees of toxicity (as determined by the minimum fatal dose for guinea-pigs of equal weight) in the proportion of 1–10. A third culture from the same colony, upon bouillon plus normal horse serum, showed an intermediate degree of toxicity. Whence the writer infers that the formation of soluble poisons in culture media is a "vital" protective reaction of the bacteria against hurtful chemical products in their environment. This immunization of bacteria finds its analogue in the fact that normally the serum of animals often contains a considerable quantity of antitoxins, for the presence of which Ehrlich and his school consider the foodstuffs responsible. This view is supported by the fact that while a colony which had been cultivated for a long time upon Löffler's serum, gave, when bred upon bouillon and upon bouillon plus antitoxin, the above results, another colony which had been cultivated for a long time upon bouillon before being bred upon bouillon and bouillon plus antitoxin, gave, when so bred, a much smaller difference in the relative toxicities. Wechsberg's results may serve to explain the apparent contradiction that certain microorganisms (for example, the typhus bacillus) which must be assumed to generate toxins within the body, do not produce any in culture media, for in the latter it is probable that they do not encounter bodies present in the former, against which they react protectively by the secretions of toxins.

Maternal Emotions in the Fœtus.

In the *Comptes rendus des séances de la Société de Biologie* (Séance of January 17, 1903), Ch. Féré, remarking that sensory stimuli and emotions experienced by the mother during pregnancy can react upon the nutrition of the fœtus, causing various disturbances of development, most frequently in the nervous system, and that from the fourth or fifth month such stimuli and emotions can also have immediate effects in the way of movements of the fœtus, cites the following case: A woman, aged 34, of non-neurotic family and personal history, and whose husband was healthy and sober, first became pregnant at twenty-two, and then, after presenting, like her mother and sister, the peculiarity of menstruating till the seventh month, gave birth to a healthy and vigorous daughter. Seven years later, approaching the window, she came face to face with a man who cast himself over the balcony of the fifth floor into the street. She then felt a series of shocks in the abdomen, which she recognized as the so-called spontaneous movements of a child. She had menstruated several days before, and had experienced no symptom of pregnancy. During the previous six months she had taken on fat which had sufficed to her to explain the increased size of the abdomen. The result showed that, at the moment of the emotional shock which left no traces on her, she was six months pregnant. She was delivered of a boy, who was entirely normal at birth, but, beginning from the third month, he began to experience sudden pallors, sometimes with stiffness in the limbs; and at eight months he had two severe convulsive attacks. After an interval of eighteen months he suffered a relapse, with sudden pallors, abrupt general or partial tremblings, general convulsions, with loss of consciousness, and other epileptic phenomena. The author considers that the case shows that the fœtus really can be affected by the emotions of the mother, without doubt reacting to abrupt alterations in the uterine pressure. These shocks are probably accompanied by other phenomena of reaction, which leave traces, and can be responsible for post-natal troubles.

Child Labor Bills.

The Child Labor Committee has prepared bills for the restriction of child labor. The Senate bills, four in number, were introduced by Senator Hill of Buffalo; three Assembly bills were introduced by Mr. Finch of New York, and one by Mr. Agnew of New York. Their most important provisions are the following: (1) In order to secure a certificate allowing employment in factories and mercantile establishments the parent of a child must file with the Board of Health incontrovertible evidence that such child is actually fourteen years of age or upward. The forms of evidence specified in the bills are: A transcript of the child's birth certificate, or of its baptismal certificate, or some religious record or passport. In addition, the school record of the child, called for under the present law, must now include a statement of the child's age as entered on the school records. The only evidence of age called for under the present law is the affidavit of the parent. (2) The existing laws prohibiting the employment of children under fourteen years of age in mercantile establishments, and regulating the hours of employment of such children, between the ages of fourteen and sixteen, are extended to cover children employed in connection with telegraph, messenger, delivery or other offices, and hotels, restaurants, and places of public amusement. (3) The provision in the existing law is repealed which allows vacation work in factories to children fourteen to sixteen years of age, who have not had the full schooling required for securing employment throughout the entire year, and the corresponding provision is repealed which allows vacation work to children twelve to sixteen years of age in mercantile and other establishments named in Section 2. This latter repeal, however, applies only to cities of the first and second class. (4) The employment of children between fourteen and sixteen years of age more than nine hours in any one day is prohibited in factories, mercantile and other establishments named in Section 2. The existing laws place a ten-hour limit, but add as an exception that such children may be employed more than ten hours in any one day if this is done in order to make a shorter work day of the last day of the week—an exception which makes the law almost impossible of enforcement. (5) No child under ten years of age shall work as a newsboy, bootblack, or street peddler in cities of the first class, and no child ten to fourteen years of age shall so work later than nine o'clock in the evening.

The Medical Record has been active in advocating a revision of the laws regulating child labor.

The bills prepared by the Child Labor Committee seem to be drawn up in such a manner that if they become law will do away with most of the disgraceful features of the present system. It is well that New York should lead the way in inaugurating these much-needed reforms, an example which many other States should be quick to follow.

Filthy City Dogs.

So much favorable comment has been made upon our recent notice of the city dogs' extensive use of the pavements for purposes other than those of walking and running, that we are led back to the subject.

The facetious remark of a contemporary that perhaps we had put our editorial foot into it needs no answer. The first step having been taken, we shall once more urge the authorities to tender some relief. If all dogs were healthy the matter might not appear so bad, but for some unknown reason 75 per cent. of city dogs have been found to suffer from diarrhœal troubles. Magistrate Crane has become interested in the dog question in general, and in a recent decision drew tears from a young lady dog-fancier by his remarks upon the superiority of children over dogs in the household.

Dogs may be well enough as household pets in the country, where they can run at times and dig holes in the soil, but in the hard and stony paved city they prove a constant menace to the pedestrian by day and night. If any one thing ever brings about a war of the classes it may be the indifference shown toward the walking public by the rich dog owners who always ride, but use the pavements for their pets' unlawful and immodest purposes.

The Treatment of Gallstones by Cholagogues.

In the *Correspondenz-Blatt für Schweizer Aerzte*, for February 1, 1903, Dr. Rob. Glaser urges the cholagogue treatment of gallstones in preference to operation. He criticises the infection theory of the disease, reasoning that, as normal bile is sterile, infection must be secondary to some abnormal composition of the fluid, which abnormality he refers back to a derangement of the secretory nerves (vagus and sympathetic), and concludes "that cholelithiasis from first to last is a nervous and not an infectious disease." The keynote of treatment is to re-establish the normal proportions among the several constituents of the bile. He then discusses the various cholagogues. Oils, soaps, ether, and the like are of no value, as they do not appear in sufficient amount in the bile. Also the salts of the bile acids are of no value. After twelve years' experimentation, the author has settled down to different combinations of mercury with aromatic vegetable extracts of the purgative-cholagogue group (podophyllum), and of carminatives and antispasmodics and oils (melissa, camphor, caraway). The individual susceptibility is to be gauged, it being desirable to have one to two stools per day. The most obstinate constipation is often simultaneously relieved. An excellent palliative during the paroxysm is a flannel bandage saturated with ol. papav. and chloroform, āā, covered with a piece of batiste. He never uses morphine, but often gives tincture of belladonna, eight to ten drops. Treatment is to be followed for three to four months. Jaundice is a favorable symptom, as it indicates the descent of the stone into the ductus choledochus and the accessibility of bile to the gall-bladder. In addition to medicinal treatment, such measures as the greatest possible relaxation from the daily cares, abundant exercise in the open air with repeated deep breathing, careful regulation of the diet, warm baths, and, in the beginning with chronic cases, rest in bed, are indicated. He then analyzes briefly his first hundred cases, of which 78 per cent. were cured, having no further attacks and being able to work and to stand all articles of diet without difficulty. Of the remaining 22 per cent. 16 per cent. were improved, and 6 per cent. showed no definite result. There are no contraindications for this method of treatment.

Smallpox in Indiana.

In the *Indiana Medical Journal*, March, the widespread prevalence of smallpox in Indiana, and especially the situation as regards the epidemic in Indianapolis, is made the subject of editorial comment. Although smallpox has been present in Indianapolis for the past three years on a comparatively large scale, the disease has been of a mild type and the mortality has been correspondingly small. Since December, last, however, smallpox has exhibited much of its old-time virulence, 100 deaths out of 600 cases having occurred. The editorial in the *Indiana Medical Journal*, states that every form known in the clinical history of the disease has been observed—discrete, confluent, with death from sepsis, as well as the malignant and hemorrhagic varieties.

The most distressing feature of the existing epidemic in Indiana is, according to the *Indiana Medical Journal*, the indifference of the population of the State to the condition of affairs, the neglect of vaccination, and the constant errors in diagnosis. The editorial in question passes some scathing criticisms upon the State Legislature of Indiana, which negatived a Supreme Court decision, permitting compulsory vaccination in times of epidemic by attaching a proviso to the compulsory education law that "children in good mental and physical health, any rule or law to the contrary notwithstanding, shall not be kept from admission to the public schools."

It is a distressing fact that a very large number of persons are ignorant of the comparative immunity conferred by vaccination and revaccination. Distrust of and prejudice against the method has been aroused by anti-vaccination agitators, and perhaps a severe epidemic of smallpox is needed to open the eyes of the community to the danger which is now blindly disregarded. After all, it is experience that teaches. The lesson may be bitter, but it is generally effective.

International Congress against Alcoholism.—According to the *British Medical Journal*, March 14, the International Congress for the suppression of alcoholism will hold its ninth annual meeting at Bremen from April 14 to 19. Among the speakers during the six days' discussion will be Lady Henry Somerset, and Mr. von Diegardt of Majawola, who will deal especially with the question of public-house trusts and the reform of public houses in England and Germany, and Mr. Fitger of Gothenburg, who will speak on the subject of the Scandinavian system. Among other communications promised are: "Alcoholism and Tuberculosis," by Dr. Legrain of Paris; "Alcohol in the Life Process of the Race," by Dr. Plotz of Berlin; "Alcohol as a Food," by Drs. Fraenkel of Halle and Forel of Morges; and "Alcohol in the Budget of Civilized People," by Dr. Helenius of Basle. Full details as to the arrangements may be obtained from the Burgomaster, or from the Secretary, Dr. jur. H. Eggers, 30 Osterthor Strasse, Bremen.

News of the Week.

Fourteenth International Medical Congress and French Railroads.—The following information has just been received by cable from the Secretary-General of the Fourteenth International Medical Congress:

"The French railroads have made their rate reductions for the members of the International Medical Congress depend on a special certificate and on the use of the same route for going and returning. Any member of the Congress to whom this is of interest should, therefore, write immediately to the Secretary-General at Madrid, stating at what port he expects to land and what route he will take. The Secretary-General will send to him at the port named under the address *poste restante* the necessary certificate."

Pathological Society of Philadelphia.—At a stated meeting, held March 26, Dr. Jos. McFarland exhibited a specimen of spontaneous rupture of the heart. The organ exhibited merely a short linear laceration in the wall of the left ventricle, without other obvious lesion. The pericardium contained a moderate amount of clotted blood, which evidently had escaped in small jets and not in the form of a massive hemorrhage. Dr. McFarland exhibited also a specimen of aortic aneurysm with rupture into the left bronchus. The aneurysm was a large spindle-shaped dilatation of the descending portion of the arch and the thoracic aorta. Dr. McFarland exhibited a further specimen of aneurysm of the aorta perforating into the spinal canal. The patient presented during life symptoms of myelitis, which, in the presence of angular curvature of the spine, were attributed to spondylitis. Death occurred from rupture into the pleural cavity, and post-mortem examination disclosed a large sacculated aneurysm of the thoracic aorta, which had eroded the bodies of several dorsal vertebræ, and had caused compression of the spinal cord. Dr. Richard M. Pearce presented a communication entitled "The Development of the Islands of Langerhans in the Human Embryo," relating the results of a histologic study of the pancreas in fetuses from the age of seven weeks to that of seven months. He was able to follow the development of the islands from the acini of the gland through successive stages and up to their separation and isolation. Dr. Edward K. Dunham of New York presented by invitation a communication entitled "Some Observations Concerning the Physical Characteristics of Nutrient Gelatin, with Especial Reference to Their Influence upon Colonies of Bacteria," and he illustrated his subject with a series of lantern slides. His studies showed differences in colonies in accordance with the quality of the gelatin employed, the method of preparation, the temperature to which the gelatin was subjected, as well as the time of exposure, and, more particularly, its viscosity.

Philadelphia County Medical Society.—At a stated meeting, held March 25, a symposium was held on the subject of "Anæsthesia." Dr. G. G. Davis read a paper entitled "The Choice of an Anæsthetic," Dr. John G. Clark, one on "The Preliminary Preparation of the Patient"; Dr. Edward Martin, one on "Methods of Administration of Anæsthetics," and Dr. G. W. Spencer, one on "Treatment of Complications Arising During Anæsthesia."

Philadelphia Neurological Society.—At a stated meeting, held March 24, Dr. T. H. Weisenburg exhibited a case of progressive bulbar palsy. The symptoms were confined to the distribution of the bulbar nerves and were attributed to a lesion involving the bulbar nuclei. Drs. S. S. Kneass, W. F. Hendrickson, and Jos. Sailer reported a case of tuberculous meningitis with secondary Infection. The case was for a time considered one of typhoid fever, but the existence of leucocytosis, together with the presence of cerebral and spinal symptoms, and the results of lumbar puncture, led to a diagnosis of meningitis. Death resulting, the lesions of meningitis were found, and from these both the tubercle bacillus and the micrococcus tetragenus were obtained. Dr. Chas. W. Burr read a paper entitled "Hemiplegia without Gross Lesion in a Case of Plumbism and Nephritis." It could not be decided to which of the etiologic factors the hemiplegia was due, but it was thought that it might have resulted from the disease of the kidneys, which in turn could be attributed to the lead-poisoning. Dr. E. Lindon Mellus demonstrated a hitherto undescribed nucleus in the medulla. This consisted of a group of cells near the olivary fasciculus in the dog, and corresponding to a smaller group of cells in the medulla from a human being. The identity and the function of this nucleus have not yet been determined. Dr. G. M. Dorrance exhibited a case of complete brachial monoplegia. The patient was a colored man who had been struck on the shoulder by a bucket that had fallen from a great height. There was complete paralysis of the arm with wasting, complete reaction of degeneration, and anæsthesia. The patient had burned himself without being conscious of the fact at the time. The question was raised whether amputation of the useless member should be performed, but it was suggested that an examination of the brachial plexus first be made with the hope that some less radical procedure might be necessary.

Health Department, New York.—Dr. F. H. Dillingham, after a service of twenty-one years in the Health Department, for ten years of which he was assistant sanitary superintendent, has resigned with a view of devoting himself to private practice.

Accident to German Empress.—It is reported from Berlin that, on March 27, the Emperor, Empress, and suite started in the early morning for their usual ride. Soon after entering the Grünewald Wood, the horse on which the Empress was mounted stumbled, throwing her Majesty, who fell on her left arm, sustaining a simple fracture just above the wrist. Surgeons were telephoned for, Dr. Zuncker arriving first in an automobile, having made the journey from Berlin at the rate of forty miles an hour. The arm was set in plaster of Paris.

Hydrophobia among Horses.—In Wisconsin hydrophobia is stated to exist among cattle and horses in almost every part of the State. The situation is said to be so grave that State Veterinarian Roberts has refused to order any more animals to be killed, on account of the expense, as the owners of diseased cattle killed are indemnified for their loss.

Home for Nurses of the Presbyterian Hospital.—A home for nurses, at the cost of $300,000, is to be built as an annex to the New York Presbyterian Hospital. One of its features will be a large gymnasium at the top of the building.

An Act to Create the Office of Medical Inspector.—An amendment to the Insanity Law of New York State has been introduced into the Assembly, reported and referred to the Committee on Revision. The portion of the amendment that refers to the

medical inspectorship is as follows: The Commission in Lunacy may appoint a medical inspector who shall be a well-educated physician, a graduate of an incorporated medical college, and who shall have had actual experience in an institution for the care and treatment of the insane. Such inspector shall receive an annual salary of five thousand dollars and traveling expenses, and shall visit and inspect the State Hospitals and other institutions which are subject to the supervision of the Commission.

Control of New York State Hospitals.—The bill, introduced by Senator Ramsperger and Assemblyman Morgan for further centralizing the management of State Hospitals has been passed by the Senate. The bill provides for the appointment by the State Lunacy Commission of a treasurer for all the State Hospitals, thereby doing away with the supervision now exercised by local treasurers over the financial operations of the commissioners. It also provides for the purchase of staple supplies for which contracts are now made by the stewards "by an agent appointed by the Commission for that purpose."

Abolition of Coroner.—The Coroner Abolition Bill, as explained by the representatives of the County Medical Association, shows what a fifth coach-wheel the Coroner is. His investigation into the cause of death is properly the task of the Health Department, and his investigation into the criminal aspect of a death is properly the function of the District Attorney. The abolition of the Coroner will be true political reform.—*New York Sun.*

The Diplodocus Carnegiensis.—The story goes that when the King of England visited Andrew Carnegie at Skibo last year, he was much impressed with the picture of a huge fossil reptile, and asked his host what it represented. "That is a namesake of mine, "said Mr. Carnegie, "the Diplodocus Magnifissimus Carnegiensis." The King remarked that he would like to have a diplodocus, and it is reported that Professor Hatcher of the Section of Paleontology of the Pittsburg Carnegie Museum is putting together the fossilized bones of one excavated in Wyoming. It is further reported that this relic of the past will be a gift from Mr. Carnegie to the British Museum.

An Amendment to the Insurance Law of New York State.—This amendment provides that any corporation organized under the laws of this or any other State or country, and doing business under the regulations of the insurance law of this State, shall be permitted to conduct or provide under contract executed prior to the death or sickness of any person, and agreeing, upon the payment of any stated sum of money, either weekly, monthly, or at any other time, to provide burial in case of death, or medical attendance and medicine in case of sickness, of any such person. Such corporations to be subject to the supervision and control of the Superintendent of Insurance, and to all the provisions of the insurance law or any other statute relating to health and casualty insurance corporations.

Christian Science in North Carolina.—A bill drawn up at the request of the North Carolina State Superintendent of Health, to prevent the practice of faith-healing in the State has been defeated. The bill defined the practice of medicine and surgery to be the treatment for fee or reward of any cases of disease, "physical or mental, real or imaginary," with or without drugs, surgical operation, or by any other method whatsoever, and prescribing the usual qualifications of physicians as those necessary to obtain a license so to practise. The bill was defeated by the adoption as an amendment of a provision specifying that the act should not apply "to any person who ministers to or cures the sick by prayer to Almighty God without the use of drugs or material means."

An Act to Amend the State Charities Law.—An act to amend the State charities law, relating to the finances of the State charitable institutions, reports of managers or trustees, purchases and advertising for proposals, has been introduced into the Senate of New York State, read twice and ordered to be printed and committed to the Committee on the Judiciary. The alterations in the existing law are slight.

Mosquitos Expected Early This Year.—If the anticipations of Dr. Joseph H. Raymond of the Brooklyn Health Board be realized, mosquitos will be both earlier and more numerous than usual this year. It is predicted that if the warm weather continues there will be many mosquitos on the wing within two weeks.

Insurance of a Christian Scientist.—A Christian Scientist named Robb died a short time ago at Lansing, Mich. The widow claimed from the Foresters $1,000 on an insurance policy. The proofs sent, however, in support of this claim, showed that although he had been seriously ill for two weeks no physician attended him until the day before his death. The Foresters have refused to settle the claim, under the section of their Constitution which withdraws the benefits of insurance from any who neglect to procure or refuse to receive medical aid.

Warning the Poor against Pulmonary Cures.—In order to discourage poor persons who suffer from pulmonary complaints from patronizing concerns which profess to be able to cure consumption, the Tuberculosis Committee of the Charity Organization Society has issued a large number of circulars, which it has caused to be distributed among the poor. This is both a wise and humane proceeding on the part of the organization, as many of such concerns are brazen frauds, which by means of speciously worded advertisements, lead ignorant persons to suppose that they can really be cured of consumption by following the treatment and advice of those who manage these establishments.

New Hospital for Greenwich, Conn.—A meeting was held at Greenwich on March 27, called at the instance of the Greenwich Medical Society, and presided over by A. Foster Higgins of New York, for the purpose of starting a movement for the erection of a hospital in Greenwich. It was decided to raise $100,000, of which $30,000 has been already subscribed, before any work was started.

Rush of Immigrants.—"It looks," says the New York *Sun*, "as if immigration for April and May will be pretty close to the record at this port. Already the figures for last March, 54,000, have been eclipsed, 63,000 home-seekers having landed at Ellis Island in the last twenty-nine days. The liners *Graf Waldersee*, *Philadelphia*, *La Savoie*, and *Campania* brought in 4,569 on March 28, while during the week 22,000 immigrants are due, more than half of whom are from Italy.

Smallpox among Digger Indians.—An epidemic of smallpox is reported to be raging among the Digger Indians of Long Valley, Cal., which threatens to exterminate the tribe. The Indians are living in their native state, and rely on their medicine men for advice and treatment. Their custom is to dance in tightly closed mud huts until exhausted, and then plunge into a nearby river. This treat-

ment has had a decidedly disastrous effect, and the disease is said to be spreading widely. Up to the present all efforts to induce the Indians to submit to vaccination have failed.

Lunacy Spreading in London.—In a report presented to the London County Council on March 9 by its Asylum Committee, it was pointed out that the Council was responsible on January 1, 1903, for the accommodation of 16,961 lunatics. The number of beds now provided in the London asylums is 16,379, 1,400 of which being in temporary buildings. "There is, therefore," the report continued, "at the present moment considerable deficiency of accommodation. The average annual increase of lunatics in the county of London since 1890 is 527, but the average for the past five years is 576.

The Manhattan Eye and Ear Hospital has made a public appeal for contributions to a fund of $100,000, which must be raised before January 1, 1904, in order to receive a like amount, for the purpose of removing from its present building, at Forty-first street and Park avenue, to more modern and more spacious quarters.

Woman 132 Years Old.—An extraordinary case of longevity is reported in the *New York Herald*, March 24. Mrs. Mary Murphy of Kerrtown, Mercer County, is declared to have celebrated her 132d birthday anniversary on that date. She was born in Dublin, Ireland, and has been married three times. She has always drunk tea and coffee, and takes a drink of whiskey occasionally.

Street Peddlers to Be Abolished.—It is stated that a movement is on foot to do away with the numerous peddlers who infest the streets of New York. Dr. McGaw Woodbury, the Commissioner of Street Cleaning, is said to be extremely anxious to put an end to the pushcart industry, on the ground, especially, that it is a menace to the public health. There are 11,000 licensed pushcart peddlers in Manhattan and The Bronx.

Radium Throws Off Heat.—M. Curie, the eminent French physicist, has just made the communication to the French Academy of Sciences, that radium possesses the property of continuously emitting heat without combustion, without chemical change of any kind, and without any change in its molecular structure, which remains spectroscopically identical after many months of continuous emission of heat.

International Congress of the Medical Press.—This Congress will be held in Madrid, April 20 to 22, 1903, immediately preceding the International Medical Congress. The same reduced rates upon railroads will be extended to those attending the latter as to members of the former. The congress will be made up of members and associate members; those eligible to membership will be medical editors and their collaborators and also editors of pharmaceutical, odontological, and veterinary journals. Among associate members will be included editors' families, doctors, and students of medicine. The subscription for the former will be 25 pesetas; for the latter, 10 pesetas. Prominent among the subjects for discussion will be the formation of an International Medical Press Association, and the application of copyright to medical literature. All communications relating to the congress, as well as subscriptions, should be sent before April 15, 1903, to the Secretary General of the Committee on Organization, Dr. Larra y Cerezo, Leganitos, 17, Madrid.

Obituary Notes.—Dr. D. Gilbert Gordon, a well-known physician of Toronto, Canada, and brother of the Rev. Charles W. Gordon, known in literary circles under the "nom de plume" of "Ralph Connor," died on March 28, in Baltimore, of peritonitis. The late Dr. Gordon was forty-four years of age, graduated in arts from the University of Toronto in 1883 and in medicine from Trinity College in 1887. In 1888 he took post-graduate courses in Edinburgh and London.

Dr. John P. Wood of Coffeyville, Kan., died at Thomas, Okla., on March 28, at the home of his brother-in-law, David Garvin, at the age of 101 years and two months. Dr. Wood was a practising physician for seventy-five years and was the first Probate Judge of Douglas County, Kansas.

Dr. William Henry Crosse, who for nine years was medical officer of the Royal Niger Company and a recognized authority on tropical diseases—especially on blackwater fever—died in London, February 24, at the age of forty-five years.

M. Louis Leblanc, a member of the French Academy of Medicine, died suddenly on March 9, in Paris.

Dr. Jonathan Cilley, a well-known army surgeon during the civil war, died at his home, Forty-fourth Street and Twelfth Avenue, Borough Park, on March 18. Dr. Cilley was demonstrator of anatomy at the Ohio Medical College, when the body of John Scott Harrison was stolen from the graveyard in which it was interred and sold to Ohio College. The body was recovered and Dr. Cilley proved that it was sold to the College with several others.

Dr. Robert Safford Newton, the well-known alienist, died at his home, 19 East Forty-fourth street, on March 25. Dr. Newton was born in Cincinnati in 1857 and came to New York when a child. He was graduated at the College of Physicians and Surgeons, and also studied in Europe. The diseased physician gave expert evidence in several celebrated cases, including the trials of Roland Molineux, Marie Barberi, and David Hannagan.

Dr. Charles H. Jones died on March 27, at 410 Ninth Street, Brooklyn. He was graduated from the Long Island College Hospital in 1899. He served during the Spanish-American War as a Captain in the One Hundred and Fourteenth Regiment New York Volunteers.

Dr. Thaddeus Mead, one of the oldest dentists in Orange County, died suddenly on March 29, at his home in Port Jervis, at the age of sixty-two years. He served in the Civil War in the Seventy-first New York Regiment.

Dr. Russel P. Fay of Yonkers died at his home there on March 30. He was a leading homeopath, and was once President of the Westchester County Homeopathic Medical Society. The late Dr. Fay was a member of the American Institute of Homeopathy and of the New York Homeopathic Society.

Senator Enrico Bottini, one of the best known Italian surgeons, and for some time professor of operative surgery in the University of Pavia, died on March 11, at San Remo. He was born at Stradella in Piedmont in 1837. At the age of twenty-eight years he was appointed Obstetrician and Surgeon-in-Chief in the Ospedale Maggiore at Novara. The deceased was chiefly known for his studies in galvanocautery, and by the splendid results he obtained by this method, especially in angioma of the face. In 1887 he was elected as a deputy to the Italian Parliament by his fellow townsmen of Stradella, and in 1891 was made a Senator of the kingdom. Failing health necessitated his retirement from active duties for a considerable time before his death. He was buried in his native town of Stradella.

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent.)

ROYAL MEDICAL BENEVOLENT COLLEGE—SICK POOR, HOSPITALS AND NURSES—EXCRETION OF SODA IN RENAL DISEASE—RELATION OF URIC ACID TO LEUCOCYTOSIS—EHRLICH'S TESTS—MEDICAL PORTRAITS—BRITISH ASSOCIATION—ALBERT MEDAL—MEDICAL DINNER—SMALLPOX—THE LATE DR. CROSSE.

LONDON, March 13, 1903.

A GREAT effort is being made to put the Royal Medical Benevolent College on a better financial foundation. The Prince of Wales will preside at the dinner in June. The college provides pensions for aged medical men in reduced circumstances, and for needy widows. There is also a school, open, indeed, to all classes, but in which the sons of medical men are educated under special terms—fifty foundation scholars being educated, maintained, and clothed. The committee is appealing for £10,000 as a jubilee fund to pay off its liabilities and make a fresh start. They deserve to get it, and I hope they will; they ought to get as much yearly.

The annual financial statement of the Metropolitan Asylums Board shows that the gross expenditure approach two millions sterling—a sum to give pause to the ratepayers. Smallpox is credited with £596,000; from which, however, is to be deducted £166,000 for works in progress before the outbreak, but all of it for hospitals. The money borrowed equals £4,500,000. With all this, the Chairman of the Finance Committee declared that "no public body was more free from extravagance; they did not spend money to advertise themselves with ornate and highly decorated buildings; the work they undertook was always necessary." In this little speech you may see one source of the burdened ratepayer's groans. Buildings and other extravagances accumulate, and his patient shoulders have to bear it all; but there are ominous murmurings which may one day break out in unexpected rebellion against the injustice. This very Board was asked to undertake the care of consumptives. To do so might exceed its authority and the proposal was postponed.

The Parliamentary Secretary of the Poor Law Board opened a new infirmary for the sick poor on Saturday. It is equipped with all modern improvements and has cost the parish £100,000 which comes out at about £300 per bed. No one grudges the sick any comfort, but many ratepayers are asking whether there must not be extravagance when a building runs to such a sum. The Secretary boasted that the energy of his Board was always directed to improve the accommodation for the poor, and that they had increased the nurses by 44 per cent. He wanted the poor to regard the "work-houses" as their own "rest houses," and seemed to be unconscious that there are paupers who will not work—although quite able to do so. Many honest ratepayers object to see these dishonest loafers treated as well as the unfortunate deserving or sick poor. The subject bristles with difficulties. It was brought before the Poor Law Congress, which has been sitting in London this week, by Mr. Sidney Holland, who said every board of guardians should be compelled to employ only trained nurses, and condemned the plan of the Departmental Committee for setting up an inferior grade, to which I lately referred. Then he went on to insist on paying them well and giving them good increases of pay every five years and then pensions. All this is pleasant enough for nurses to hear, but ratepayers are not so pleased.

Mr. Holland is Chairman of the London Hospital Committee, on behalf of which he is now making an earnest appeal for a large sum of money. No one doubts the need of that hospital—the largest in the kingdom—but many think that there is need of reform in its administration. There is a very unsatisfactory state of the Out-patient Department. As I mentioned to you, some £70,000 has been spent on this in the past year, and hospital reformers think this uncalled for, and therefore extravagant. But the Department gives Mr. Holland figures for his sensational—not to say quackish—appeal. So many thousands of sick! Then he reckons how many miles they would make standing side by side, and how many tons of pills they have swallowed. It is rather nauseating and encourages the notion that the more patients who can be reported to have come, the greater will be the response of the charitable public. But the other side of the subject is disheartening. It is hospital abuse, say the reformers, and one governor of this hospital said to me that Mr. Holland's outcry was rather for "help to pauperize the East End."

The general feeling that the hospitals should be distributed over a wider area receives more attention since the proposal to remove St. Bartholomew's has been discussed. It is now the turn of St. George's to be talked about in this respect, and as this institution is also in want of money, some of its governors think it might be removed from its present valuable site. The plan, it is thought, should be considered now, as the space is very restricted and the managers think enlargement necessary. There is no certainty that a suitable site could be found in the West End on terms to make removal economical. This tendency to expansion among hospital managers should be checked, as it leads to debt and extravagance The hospital has done good work, and all the space it needs could be obtained by removing the school and nurses' homes to less expensive, but not distant quarters.

Dr. Herringham read a paper at the Pathological Society on the excretion of sodium and potassium in renal disease. He rejects Bouchard's explanation of the toxicity of urine. He is of opinion that uræmia is not connected with toxicity of urine—is not due to retention of any normal product, but rather to something abnormal. He anticipated that if any marked change occurred in the urine in nephritis it would be in the excretion of potassium, but he found, on the contrary, great variation in that of sodium. He made sixteen analyses in eleven cases of chronic interstitial nephritis, six of them fatal. In every one of the six excretion of sodium was very small or *nil.* But this was not so in the five non-fatal cases. He also made twenty analyses in nine cases of parenchymatous nephritis, of which two were fatal, and both of these showed complete absence of sodium on one or more days; in the other seven which recovered this was not the case.

Thinking the result might be due to diet, or that the sodium might be excreted in the fæces, he analyzed diet, urine, and fæces for a series of days, but found no sodium excreted. If these results should be confirmed, the absence of sodium would impart a fatal termination. The retention could not be due to inability to excrete sodium while potassium was freely passing. Dr. Herringham found the same symptoms in two cases of ascites which had been frequently tapped. It has been obtained by Salkowski in acute fevers.

Dr. Garratt thought sodium salts were retained in renal disease for osmotic purposes. He referred to Prout's observation that it was retained in persons about to die, and that after death from uræmia chloride of sodium was found in excess in the tissues. In fevers, he had never found complete absence; if citrate of sodium was given it was retained until the fall of temperature, probably to neutralize some acid condition.

Dr. Robert Hutchinson referred to the retention of chlorides in pneumonia. This had been attributed to the cloudy swelling of the renal epithelium, which was common in that disease, but he doubted the observation and made some investigations as to the excretion of chlorides in renal disease. In all the cases he examined, none of which were of advanced renal disease, he found a fair amount of chlorides. He thought the absence of sodium in Dr. Herringham's cases might be accounted for by the retention of serous fluid in the tissues, owing to imperfect secretion of water which might occur in the later stages, and Dr. Herringham agreed with this view, the sodium being probably retained as chloride

Besides Dr. Herringham's paper there were two others submitted to the Pathological Society. One was a rather elaborate account, by Mr. H. W. Armit, of Ehrlich's dimethyl (p) amido-benzaldehyde reaction. This gives a red color to urine, which, when light, has no significance, but when deep seems of prognostic importance. Mr. Armit thinks it indicates tissue waste, generally in toxæmic conditions, as in those in endocarditis and pneumonia. He also noticed it in infective diseases. Full reaction is of grave import, but not necessarily fatal. He did not think the reaction due to urobilin, as some writers had suggested, but to an unidentified body which could be detected in small quantity in other secretions and in cartilaginous tissue.

It was remarked that the reaction was present in the later stages of phthisis, but in such cases the prognosis was quite as obvious clinically.

The other paper was by Dr. Williamson on the relation between the excretion of uric acid and the destruction of leucocytes. Observations were made on eleven patients, most of them with phthisis. In most, a rise of phosphoric acid followed a fall of white corpuscles with a rise in uric acid. Confirmatory evidence of increased destruction was obtained from differential blood-counts.

Dr. Halliburton said it was pretty well proved that uric acid originated from nuclein—whether from the food or from tissue metabolism. He thought too much was often attributed to the leucocytes. If all the white corpuscles destroyed in a day could be collected they would not form a mass bigger than a marble and could not furnish the amount of the day's excretion of uric acid. The

blood was only a sample of tissues. The liver, lymphatics, and other tissues furnished most of the uric acid.

Keen interest is felt in two decisions of the Council of the British Association for the Advancement of Science, viz., to invite Mr. Balfour to preside next year, and to recommend the association to meet in South Africa in 1905. The latter proposal is not unprecedented, as the association met in Canada in 1884 and 1897. But Africa is farther, and the expense may deter some of the highest authorities from undertaking the voyage. The invitation to the society from South Africa was given in 1900 during the war, and renewed on the cessation of hostilities. A South-African association, on the lines of the British, was recently formed, which shows the interest of the colonies in scientific matters. Their governments have also agreed to provide a sum of £6,000 toward the cost of the passages of the officials of the British Association and other eminent scientists, in order to make the meeting in 1905 a success.

The cartoons published in *Vanity Fair* have reached the number of 1,800. They include thirty-six doctors, whose portraits are now offered by the publishers for £2 2s. Single portraits may also be purchased, the prices varying from 6d to 2s. 6d. Thus, Sir S. Wilks is priced at 2s. 6d, Sir F. Treves at 1 s., while Sir W. Broadbent may be had for 6d.

The Albert Medal has been conferred by the King on Captain Herbert C. French, R.A.M.C., for his brave effort to save a man from drowning. The captain dived a depth of thirty feet, from the deck of a vessel on which he was travelling, the steamer going at eighteen knots and the water abounding in sharks.

The Medical Society of London celebrated its 130th anniversary on Saturday by a dinner, to which nearly 200 persons sat down. Sir Wm. Church proposed the toast of the society, to which Mr. Gould, the president, responded. The Hon. R. P. Porter, U.S.A., responded for the guests, as also did the Lord Chancellor. It was a very successful gathering.

Smallpox continues in the provinces, particularly in the northern towns of England. Most of the outbreaks are traced to tramps. Some 300 cases are under treatment at Liverpool. Dublin also has been visited. Altogether over 2,000 cases have been notified in the last two months.

Dr. W. H. Crosse died on the 24th ult. From 1886 to 1995 he was medical officer of the Royal Niger Company, and you will certainly remember his contributions to *Tropical Medicine*, particularly on hæmoglobinuric fever. In 1895 he returned to England and began practice in London, but the Royal Niger Company still had his services as their London adviser. Unhappily, he brought home an enlarged spleen and other troubles from the West Coast, which after years of invalidism, have carried him off at the age of forty-five years.

OUR LETTER PROM THE PHILIPPINES.

(From Our Special Correspondent.)

FEBRUARY 15.

It having been found that the hides of animals dead of rinderpest have been shipped from the provinces to Manila, with the apparent result of spreading this disease, the importation of hides into the city has been prohibited by the health authorities, except when these hides are accompanied by certificates that the animals from which they were taken were in a healthy condition at the time of slaughter. This action will probably not meet with the approval of the little Filipino brother, who has no prejudices against using the hides of animals dead of disease, nor even in using their flesh as food. It has repeatedly been found by Army officers that when horses, mules, and other animals dead of such diseases as glanders and rinderpest had been buried, the carcasses were promptly exhumed and used for food by the natives, the flesh in some instances being offered for sale in the markets for that purpose. For this reason, the carcasses of such diseased animals were habitually burned when fuel could be obtained. In some instances carcasses were drenched with coal oil and set on fire, but the natives did not object to the oily taste of the partly-consumed body. When complete incineration was not practicable, the most satisfactory way for preventing a carcass from being used as food was to sprinkle it with crude carbolic acid, slitting up the hide so that the acid could permeate the interior tissues. A few weeks ago the native engineer in charge of the Government Crematory at Manila was convicted in the courts of selling the flesh of diseased animals brought to the crematory for destruction. His method of procedure was to place the carcasses in the furnace, but not to subsequently build a fire under them. At night he would cut them up and sell the meat to a numerous clientele. When detected he was found to be doing a large and lucrative business, and not by any means all of his customers were ignorant of the source from which the meat they were purchasing was derived. The offending crematory man was severely punished.

The filthy habits of the natives as regards food are undoubtedly a very potent factor in the occurrence and transmission of disease. Knives, forks, spoons, and individual plates are but little used by the lower classes, the whole family squatting around a kettle of rice, from which they eat in common, and into which they plunge their unwashed and frequently infected hands. The handful of rice taken out is squeezed into a bolus, which is crammed into the mouth with the fingers. This method of feeding has been responsible in no small degree for the communication of the cholera infection to the various members of a family, gang of laborers, or crew of a boat, during the present epidemic of this disease, and is very probably responsible to a considerable extent for the great prevalence of intestinal parasites among them.

Another insanitary habit is the universal custom of handling food in the markets. All articles are picked over, pinched, hefted, etc., by a dozen possible customers before the final purchaser comes along. A group of women will squat for hours around a tray of meat, fish, fruit, or vegetables, and some one of them is constantly pawing over the contents of the tray with her dirty fingers. If it is possible to infect persons with disease through the medium of food, the insanitary habits and methods of these people will certainly insure its accomplishment. During the cholera epidemic orders were issued prohibiting this indiscriminate handling of food, but these orders were resented as interfering with a custom and a privilege, were not obeyed, and could not be enforced. In carrying home their purchases of food the Filipinos have not the faintest ideas of cleanliness as we understand it in the United States, and it is a common sight to see a woman with a tray on her head, on which, exposed to the dust, sun, and flies, is a jumbled mass of raw meat, fish, vegetables, and bananas, with usually a live chicken or duck, and sometimes a live sucking-pig mixed in with the rest. Constant sanitary inspection of the Manila public markets keeps them in a reasonably cleanly condition, but in the provinces the native revels in the filth of the primitive savage. The Santa Cruz market is kept in a particularly good condition, and the erection of its building and its proper administration is one of the notable improvements brought about in Manila by the Americans. This market was formerly held in a collection of filthy native sheds on the river bank; but with the appearance of bubonic plague in Manila these were torn down and a large airy building, with concrete floor and corrugated iron roof, erected in their place. This building, which is very large, is filled with small stalls, at which the natives do their trading, for the meat market and vegetable store or green grocery, as it exists in the United States, is practically an unknown institution in the Philippine Islands. In addition to the Santa Cruz market, there are several other markets of less importance in other parts of the city. In the provincial towns the markets are almost always simply open pieces of ground set apart for the purpose, with no shelter of any kind against sun or rain. In the little country hamlets some large tree is usually resorted to by common consent, and buying and selling goes on in its shade. Usually this trading is more in the form of barter than sales.

In this hot climate food must be soon used to prevent spoiling, hence any large quantities or large assortment of foodstuffs is rarely seen. In the larger towns, the supply of perishable foods brought from the country suffices for a single day only, and any interference with communication produces immediate discomfort and distress. Rice is about the only article of native food which bears storage, and heavy rains, epidemic disease, or anything else hindering the free flow of foods to the towns practically throws the poorer class of natives upon a diet of rice alone. Lately, a little canned fish or meat has begun to find a sale among them. As there is no ice, meat must be promptly disposed of after slaughter, and is usually cooked before rigor mortis has disappeared. Small pigs, chickens, and ducks are invariably sold alive and taken home to be killed as required. The suffering that these creatures undergo, tied by the legs and slung over a pole during a long trip from the country, does not improve the character of the food they furnish. The natives are thoroughly calloused to suffering—as an instance of which it was lately discovered that in a certain Manila market large hogs were forced to jump to the hard pavement from the carts in which they were brought into the city, with the result that the legs of the unfortunate animals were frequently broken. In this condition they were allowed to remain for from a few hours to several days without slaughter. Among the lower-class natives of the country districts, dogs are not infrequently eaten, and among the Igorrotes of Luzon they are esteemed as a special tid-bit.

The method of the latter tribe for preparing the dog for the table consists in withholding food for about two days, during which time the wretched beast is constantly beaten with bamboo sticks until its flesh is a mass of bruises. It is then given rice and urged to eat all it can hold. After the digestive processes have set in the dog is knocked in the head and roasted, hair, entrails and all, over a fire. The Igorrotes believe that by this means the flesh of the animal is made more tender and palatable, and the rice forming the contents of the stomach and intestines is esteemed as a special delicacy. With such habits of diet it is no wonder that intestinal parasites, dysentery, typhoid fever, diarrhœas, and gastritis are rife among these people.

As a general thing, the preference for a special cut from the animal does not enter the mind of the Filipino, to whom all parts, intestines, lungs, etc., are alike. The food of the lower classes is cooked almost exclusively by boiling, and meat is used but little except in the form of stews and as a flavor for the inevitable rice. Sometimes a small part of the food is fried in cocoanut oil, but broiling, baking, or roasting is rarely resorted to.

The diet of the Filipino is badly balanced. But little food of any sort except rice is eaten, and that is so deficient in protein that to secure from such a diet a sufficient amount of nitrogen it is necessary to take an excess of carbohydrates beyond the needs of the system. Immoderate quantities of rice are thus eaten, which undergoes fermentation in the intestine and predisposes to diarrhœas and intestinal disorders. The prominent bellies of the natives, especially in the mango season, when this fruit is also largely eaten, give evidence of a bulky and innutritious diet. The addition of a small amount of some such food as barley, beans, or peas to the general dietary would undoubtedly be of advantage for the laboring classes, with a slight reduction in rice component. This would give a dietary of much the same calorific value, but containing a slightly higher proportion of tissue-forming foods.

In this connection, mention may be made of a highly interesting paper, on "some of the diseases observed in the prisoners of Bilibid Prison," which was recently read before the Manila Medical Society, by Dr. L. H. Fales, formerly attending surgeon to the prison and now connected with the Board of Health. Bilibid Prison is an institution which occupies the dual position of jail and penitentiary, and is located on a tract of about eight acres near the business part of Manila. During the past year the average number of prisoners was about 2,000, of which number about 5 per cent. were Americans. During the year 1902 there was much sickness among the prisoners, 7,090 cases coming on sick report and furnishing 325 deaths. Of these 7,090 cases, 5,446, or 77 per cent., were due to beriberi, 4½ per cent. to fevers and 3½ per cent. to dysentery. There were 32 cases of cholera with 26 deaths, and 29 cases of pulmonary tuberculosis with 19 deaths. Beriberi was, by far, the most important disease during the year. All patients presenting the slightest symptoms of this disease were placed in the beriberi hospital, since it was found that these cases usually made a rapid recovery when treated in the early stages of the disease. Hence the great majority of cases observed presented a rudimentary type. Few cases of the atrophic type were observed, but the dropsical form was present in about 15 per cent. of all instances. Although the pernicious type was present in less than 10 per cent. of all cases, it was the cause of over 90 per cent. of the deaths. This type was marked by dyspnœa, weak and irregular cardiac action, cyanosis, pain in the chest, subnormal temperature and death, the last often occurring in a few hours. Many of these cases developed very suddenly.

In determining the cause of the outbreak, Dr. Fales stated that in 1901 there was very little beriberi in the prison, and during September, October, and November of that year but two or three cases. Early in December the previous ration was cut down, rice imported from Siam was issued in place of native rice, cold storage meat for native meat, and small quantities of potatoes and onions for native vegetables. Shortly after this change, in the same month, beriberi began to appear. The disease increased until the latter part of February, remained stationary in March and April, showed a slight increase in May and June, and in the next four months went up by leaps and bounds. Everything possible was done to improve the general sanitary condition of the prison and reduce any overcrowding, but with no apparent result on the prevalence of beriberi. In the latter part of October the ration was changed. The quantity of hard bread was increased from 16 to 32 ounces and vegetables from 3 to 8 ounces, while the rice was cut down from 2½ lbs. to 1 lb. Beriberi began to diminish immediately after this change in the ration, and within sixty days the number of cases of beriberi had fallen from over one hundred to fourteen; and on January 15 there were only three or four cases. To show that the change of season with decrease of humidity played no special part in the appearance and cessation of this outbreak in Bilibid, Dr. Fales submitted a very interesting chart. The outbreak appeared to refer directly to the defective ration given, though the disease was more prevalent and developed more rapidly in the rainy than in the dry season, and there was a slight excess of cases developed in the more crowded buildings. At a time when the humidity was high, an improvement in the ration was followed by an immediate and marked decrease of the epidemic, which came to an end within ten weeks.

In the discussion which followed, Dr. Lemay stated that he had been told by the Superintendent of the prison at Singapore that beriberi was always present in that institution, in spite of every sanitary effort, including change of diet. Dr. Munson called attention to the cessation of the severe epidemic in 1902 at the prison at Lingayen, about 120 miles north of Manila, as a result of changing the diet from imported rice to native red rice, and also mentioned several historic instances when beriberi had been controlled, in Japan and Cochin China, by an improvement of the ration. He was inclined to believe that a nitrogen starvation played an essential part, either as an exciting or predisposing cause, in the occurrence of the disease. Dr. Banister stated that he had come to regard beriberi as a place disease rather than one of a dietetic character, and spoke of instances in which the affection had disappeared from organizations of native troops on their removal to more healthful stations.

The general opinion seemed to be that a rice diet had much to do with the appearance of beriberi, and particularly certain varieties of imported rice. Whether this diet, so deficient in protein, was directly responsible for the symptoms of beriberi or merely reduced the vital resistance to such an extent as to permit of the grafting of an infection upon a depraved organism, or whether certain varieties of rice were affected with a fungous growth producing a toxin, or whether the fermentation of large quantities of rice in the intestine resulted in the formation of a toxin, was not yet determined.

In connection with the food question in the Philippines, it may be mentioned that the Medical Department of the Army has recently given up control of the ice machines, in the Philippines, of which there are at present about twenty in the islands. These machines will hereafter be run for the benefit of the posts in general, and not especially for the benefit of the sick, although the surgeon of the post is to have first claim on any ice manufactured, to meet the needs of the hospital. Where possible, cold storage rooms will be operated by these machines, so that a supply of fresh meat may always be kept on hand for the troops. At present, distances are so great and transportation facilities are so poor that small garrisons in some of the outlying stations receive fresh meat and vegetables only infrequently, causing some complaint, on the part of the troops. Heretofore, fresh beef and vegetables have been sent out from Manila only, but with the projected establishment of a number of small supply stations the supply of the smaller and more isolated stations will be more readily accomplished. Any lack of fresh meat and vegetables is severely felt by the soldiers, as native beef is not only unpalatable but hard to get in proper quantities at the right time, and the use of native fruits and vegetables has been forbidden to troops, during the presence of cholera, by general orders.

With the great decrease of cholera in Manila, the civil health authorities have removed all restrictions on the sale of vegetables and fruits in the markets. This is no doubt much to the comfort of the natives, who do not use imported or canned vegetables to any extent, but is a rather hazardous procedure from the sanitary standpoint, as infected vegetables are liable, at any time, to be brought into the city from country districts in which the cholera infection may still exist. Of course the soldiers receive potatoes and onions from the United States, Japan, and Australia, and when these are properly supplied the prohibition of the use of native produce is on the side of safety and works no great hardship.

In view of the vile whiskey and "beno" selling dens which have sprung up around the army posts since the canteen was abolished, the military authorities here have asked the Commission to prohibit the sale of liquors within two miles of a military post, except in the case of a few stations located in large towns. The commission now has this request under consideration. The liquor-dealers are up in arms against the request, and it remains to be seen if the W. C. T. U. element, which is directly responsible for the springing up of many of these dives, will now do anything toward their abolition. In their

opposition to the canteen, the liquor-sellers and W. C. T. U. are perfectly harmonious.

Reports from the Pathological laboratory state that the carcasses of rats turned in by the municipal rat-catchers show no signs of the existence of bubonic plague among them, although a few cases of the disease continually occur from time to time among the natives and Chinese. At this time last year, post-mortem examination of the rats captured showed about 2 per cent. affected with plague. In view of the sporadic appearance of plague among the natives, however, the work of rat-catching is still prosecuted vigorously.

The difficulties in the way of carrying out proper measures of sanitation in the Philippines have just been emphasized by the imposition of the death penalty on three Filipinos, who, during the outbreak of cholera at Iloilo, slashed a sanitary inspector to death with bolos, at Molo, a barrio of that town, in September last. The remainder of the party of which the three men just sentenced were members will soon come up for trial, and it is the general belief that they will meet the same fate as the three men already tried. The attack on the inspector was totally unprovoked. Hundreds were dying of cholera at the time, and the sanitary laws were being met with indifference and opposition. The natives failed to comprehend the necessity of rigid sanitary measures and objected to being placed to the slight expense and trouble of cleaning up around their domiciles. The men in question had been ordered to clean up their premises, which they refused to do. The inspector then stated the law governing the matter, and explained the consequences if they persisted in their refusal. This enraged the natives, with the result that they attacked the inspector with bolos. The sanitary inspectors of the United States think they have a hard time when they run up against the sharp tongue or the vigorous broom of some housewife, but their lot is happy compared with the inspectors here, who take their lives in their hands when they attempt to run counter to existing gross superstitions, national sloth, and race hatred in their efforts in behalf of the public welfare.

Progress of Medical Science.

The Boston Medical and Surgical Journal, March 26, 1903.

Extensive Cavity Formation in the Central Nervous System, Presumably Due to Bacillus Aerogenes Capsulatus.—Emma W. Mooers reports the case of a man of forty-nine years who died after having suffered from general paralysis for many years. An autopsy of the brain presented the usual condition found in advanced general paralysis; that is, marked atrophy, especially in the frontal lobes, and thickening of the pia. After the brain had been six days in formalin, frontal sections were made, the appearance of which was very striking. The whole of the cut surface showed many cavities, which varied in size from 3.5 cm. to the smallest visible to the naked eye. On microscopical examination they were found to be without a lining membrane; the smaller cavities almost invariably contained many bacilli; bacilli were found free in the brain tissue in clumps and singly. Only one kind of bacterium appeared to be present, which was morphologically and in staining reaction identical with the Bacillus aerogenes capsulatus of Welch. In the absence of any other demonstrated cause of death and in view of rapid and extensive abdominal distension, with great rise of temperature, it seems possible that the invasion of the circulating blood by the bacillus was the cause of death by the production of a toxæmia.

Bacillus Shiga in an Epidemic of Diarrhœa.—Lawrence W. Strong reports a number of cases of diarrhœa in which Shiga's bacillus was found. The cases suggest the possibility of the presence of this bacillus in the normal intestine, and that through the irritative action of a simple diarrhœa from any slight cause, or of a fermental diarrhœa from infected food, it overgrows the ordinary intestinal flora and sets up the inflammatory lesions of dysentery. Shiga's organism appears to be a transition form between colon and typhoid, differing from them in its action on sugars, peptone, and milk. Recent work has shown that this organism is visible in the soil even longer than the typhoid bacillus, and this suggests the means of distribution and production of epidemics. From the fragmentary nature of the evidence furnished by the cases under consideration no definite conclusion is justified, but the facts suggest that there must have been a common cause for a certain proportion of the unusual number of diarrhœas encountered. The one positive bit of evidence afforded is that the bacillus Shiga was present in four cases of ileocolitis. If the clinical inference that some simple diarrhœas pass into infectious diarrhœas and that the infectious diarrhœas are either fermental or ileocolitis, according to the place of lodgment of the irritating matter, is correct, then the bacillus Shiga might be the common cause sought for.

Systemic Infection Due to Natural Teeth Conditions.—D. D. Smith holds that the real cause of general disease emanating from mouth and teeth is due neither to dental caries nor disability of mastication, but to constant and perpetual infection through septic matter in foods and drink and the inhalation of toxic emanations from the persistent and abiding infection in mouths containing natural teeth. From his investigations the author has come to the conclusion that caries of the teeth is a result of environmental conditions; the treatment which he now adopts is enforced, radical, and frequent change of environment for the teeth, and perfect sanitation of all mouth conditions. In detail, the process consists of most careful and complete removal of all concretions, all calcic deposits, semi-solids, bacterial plaques and inspissated secretions and excretions which gather on the surfaces of the teeth, between them, or at the gum margins, and this is to be followed by thorough polishing of all tooth surfaces by hand methods (power polishers should never be employed), using for the purpose orange wood points charged with finely ground pumice stone as a polishing material. Applied once a month this "prophylaxis treatment" has cured or improved conditions of malaise, nervousness, inflammatory conditions of the throat, nervous dyspepsia, long-standing tonsillitis, alveolar pyorrhea, etc. It is a matter to be recognized that relief from mouth infection is to be afforded through dentistry alone. Germicides will not and cannot accomplish it. There must be positive and frequent eradication of all septic conditions of the teeth and all environmental conditions favoring toxic stagnation and germ culture in the mouth, and the after maintenance of the most perfect state of asepsis of the entire oral cavity.

Journal of American Medical Association, March 28, 1903.

The Respiratory Quotient as Influenced by Tuberculosis.—By the term respiratory quotient T. M. Aderhold and W. S. Hall refer to the volume of exhaled carbon dioxide divided by the volume of oxygen consumed. Their views are thus summarized:

(1) Time of feeding causes the greatest fluctuation of the respiratory quotient. Under favorable physical conditions it may rise to nearly 100 after the consumption of food, and may fall to about 70 during periods of fasting. (2) The respiratory interchange of gases is very much greater per gram animal per hour for the very small animals than for the larger ones. (3) Tubercular animals consume relatively less oxygen and exhale relatively more carbon dioxide than do normal animals under similar circumstances. (4) The respiratory quotient is raised under the influence of tuberculosis.

The Administration of Calcium Salts in Nephrolithiasis Due to Uric-acid Calculi.—The views of A. C. Crofton are summarized in the following propositions: (1) The uric acid of the urine is held in solution by di-sodium phosphate and is precipitated (salted out) by mono-sodium phosphate. (2) For the prevention of uratic calculi the increase of di-phosphate and the decrease of mono-phosphate is, therefore, a desideratum. This object can be accomplished by either decreasing the phosphoric acid or by increasing the sodium of the urine. (3) Calcium salts produce the desired effect by decreasing the excretion of phosphoric acid through the kidneys (*a*) by binding the preformed phosphates of the food and preventing their absorption; (*b*) by binding the phosphates of the blood and causing their elimination through the bowel. (4) The administration of sodium salts that can also produce an increase of the di-phosphate and a corresponding decrease of the mono-phosphate is to be condemned, chiefly because sufficiently large doses render the urine permanently alkaline. And this deleterious effect is not produced by the exhibition of calcium salts. Crofton prefers to give the calcium carbonate in doses of fifteen to twenty grains three times daily. The addition of this dose to a large bulk of pure water is just as efficient as the use of natural waters. The diet should be so regulated as to lead to the smallest possible excretion of uric acid.

Cyclic Vomiting in Children.—T. C. Ely discusses the mechanism of vomiting and its causes. In cyclic vomiting the vomiting is excessive, severe, protracted, and nothing can be retained by the stomach. Thirst is likewise excessive and distressing. There is no connection in an attack with diet or indigestion. There is generally a fever of indefinite type. Abdominal symptoms are quite immaterial and varied. The abdomen is generally about normal in appearance. There may or may not be constipation. The urine seems the most distinctive

feature, being loaded with amorphous urates and uric-acid crystals entirely out of proportion to the fever and other phenomena. Closer study of the urine in all cases may reveal the true cause, possibly blood examinations assisting. The detailed clinical histories of three cases are given. The author would emphasize the following points: (1) The importance of being watchful, on one's guard for the vomiting of this gastric neurosis, distinguishing it particularly from bilious vomiting and the vomiting of kidney disease and reflex vomiting, as of brain disease. (2) In children of gouty and neurotic history the three cases reported point to a toxin allied to the uric-acid series as the possible blood irritant causing the vomiting. (3) The importance in severe cases of hypodermic injection of morphine and atropine in conjunction with elimination, by high saline enema; by gavage; and in extreme cases, hypodermoclysis and even intravenous injections of saline solutions.

The Intracellular Toxins of Some of the Pathogenic Bacteria.—By the use of large incubating tanks, V. C. Vaughan has been able to obtain both pathogenic and non-pathogenic bacteria in large amounts free from the constituents of the culture media on which the germs have been grown. Perhaps the most interesting portion of his work is that relating to the bacillus of anthrax. He has obtained the cell substance of this organism in large quantity and has found that the dead germ substance, when mixed with water and thoroughly sterilized and injected intraabdominally into guinea-pigs in amounts of from 200 to 300 mg., causes death, and that anthrax lesions are found. By heating the germ substance with 1 per cent., by weight, of sulphuric acid in the autoclave at 110 for 10 minutes,complete sterilization is secured and the acid splits off a substance which, after filtration, is precipitated by pouring the filtrate into three volumes of absolute alcohol. This precipitate when collected, thoroughly washed until every trace of acid has disappeared, dried in vacuo, and pulverized, forms a snow white powder, which is soluble in water rendered feebly alkaline with sodium bicarbonate. This powder, when thus dissolved and injected intraabdominally into guinea-pigs of from 200 to 300 grams weight, in amounts of 50 mgs. or more, causes death with lesions similar to, if not identical with those observed after death from typical anthrax. It seems to Vaughan that this must be considered the specific toxin of anthrax.

New York Medical Journal, March 28, 1903.

Streptococcus and Staphylococcus Bronchitis.—J. M. Patton notes the fact that these microorganisms affect the course, duration, and severity of ordinary bronchitis, and that bronchitis due to streptococcus infection presents features which distinguish it to some extent from other forms of the disease. These features are a persistent and rather high temperature; a more or less generalized bronchial involvement presenting marked physical signs of bronchitis; a persistent and troublesome cough; rather free expectoration of heavy mucopurulent sputum, occasionally tinged with blood; occasional night-sweats; moderate rapidity of the pulse; and, aside from the disturbance from cough, a freedom from subjective discomfort rather suggestive in relation to the continuous, and, at times, high temperature. When these symptoms are of moderate severity and continuous, the differentiation from tuberculosis may be difficult, and may rest largely on the sputum examination. This is particularly true of bronchitis from staphylococcus infection alone, as its type is more subacute and less distinctive.

Intestinal Resection and End-to-End Anastomosis with the O'Hara Forceps in a Case of Tuboovarian Abscess with Appendicitis; Recovery.—The history of the case is given by G. C. Ward, Jr., his patient being a woman of twenty-six years. The length of the bowel removed was seven inches. The author speaks with strong commendation of the O'Hara forceps, calling attention to the precaution that should always be taken before withdrawing the instrument from the bowel—namely, to pass the blades carefully above and below the line of suture to insure the patency of the canal and to discover any accidental penetration of the opposite surface by a suture. He enumerates the advantages of the forceps as follows: (1) One forceps only is required for any size of intestine, while different sizes of Murphy buttons, or La Place forceps, are needed. (2) It is not necessary to ligate or clamp the bowel as with the button or other methods, as the O'Hara forceps keeps the intestine closed at the site of the resection throughout the operation. (3) No manipulation or work inside the bowel is done, so that the advantage of cleanliness is one of the strongest points in its favor. This is an advantage not possessed by any other method. (4) Perfect control of the work, the slippery intestines being held with great ease and allowing accuracy of suturing. (5) Simplicity.

Opium in Surgery.—E. W. Lee finds various indications for the use of opium in surgery. In fractures morphine is especially indicated. It relieves the immediate pain, brings about muscular relaxation, and abates many distressing symptoms. In severe burns it is a blessing. It is the first remedy indicated in traumatic shock or surgical shock if accompanied by pain or hemorrhage. It should be given hypodermically before the administration of anæsthetics, especially if the patient be an alcoholic, or suffering from fever and nervousness. Lee does not believe it is dangerous in abdominal surgery, provided it is possible completely to clean out the intestinal tract and to relieve the liver, lungs, and kidneys of any existing congestion. It is the best internal hemostatic. When the bleeding is complicated by restlessness, morphine is absolutely indicated because of its quieting effect on both mind and body. Obstinate and exhausting vomiting after ether or chloroform is often relieved by a hypodermic of morphine. Under many conditions he still believes in the old teaching of Alonzo Clark in regard to the use of morphine in peritonitis. He considers that the patient demands mental, anatomical, and physiological rest. With surgical procedures he believes that rest can be promoted and carried out by hot applications, flaxseed poultices, or anything to maintain heat constantly, or, if desired, cold applications. But there should be some application made to the abdominal surface. Of course the free administration of cathartics is indicated to a certain extent; but after they have accomplished their purpose, he believes the parts should be put at rest and maintained in that condition by the judicious use of opium; and he believes the time is coming when this will be considered the proper treatment in peritonitis, and that more suffering will be relieved and more lives saved than by the active treatment with cathartics, which is generally prescribed to-day.

Medical News, March 28, 1903.

How Easily We Can Be Mistaken in the Diagnosis of Cancer of the Stomach.—Mark I. Knapp reports two cases in which there were noted what are alleged as being the "cardinal" symptoms of cancer. There were pain and chocolate-colored vomitus. But, in fact, the cases were both excellent examples of "gastrosia fungosa." In the writer's own case, the nature of the chocolate-colored stomach contents was due to the immense crop of the dark-red mold variety. The other case brought up bright-red blood. This undoubtedly came from somewhere between the stomach and the oral cavity. Hemorrhage from erosion—ulcer—of the œsophagus is not a rare occurrence in organacidia gastrica. The diagnosis in these cases should not be made on "What else could it be?" Diagnosis of cancer of the stomach must never be made unless a test meal examination is made (test breakfast). It must be remembered what an apparently grave clinical picture gastrosia fungosa may give. Chocolate-colored vomit does not necessarily mean blood. A tumor may be nothing more than a spastically contracted pylorus. The writer terms these spastic contractions "stenosis pylori ab irritatione."

Spinal Concussion, So Called.—Carl E. Black declares that in railway surgery, or under any circumstance of violent and sudden shock or jarring, there are added psychical elements which may far outweigh the true pathology. It is the duty of the surgeon to use every possible means to eliminate these psychical elements from the case, and to discover, if possible, the true extent of the pathological lesion. A given case may be entirely psychical and have no pathological lesion. The following classification of injuries produced by concussion of the spine is presented: Primary effects—(1) sprains; (2) contusion of the spinal cord; (3) minute hemorrhage into or around the cord. Secondary effects or complications—(1) shock or collapse; (2) acute hysteria; (3) neurasthenia; (4) chronic hysteria. In dealing with a case, the distinction, if possible, must be made between a sprain, a contusion and a minute or capillary hemorrhage. The understanding of these cases will be much more rational, and the treatment far more appropriate, if hemorrhage is accepted as the basic lesion. If it is positive that there has been no hemorrhage or sprain or contusion, then the case is purely psychical, and should be treated as such. It is the duty of every surgeon to protect himself, as well as the corporation he represents, and the best interests of his patient, by distinguishing, to the best of his ability, between the purely psychical, secondarily psychical, and the truly pathological condition, and to treat the case accordingly.

The Operative Treatment of Fracture of the Patella.—Russell S. Fowler says that there are a certain number of cases of fracture of the patella in which operative treatment is contraindicated. These cases are to be treated

by apparatus. They include those suffering from intercurrent disease of such a nature as to prohibit operative interference of any kind, and who prefer to pass the remainder of their lives partly disabled, rather than to risk an operation, the mortality of which, though small, still does exist. Longitudinal fractures do not require operation; in comminuted fractures operation is advisable, except in selected cases, when circumsuture may be employed; neither do transverse fractures in which rupture of the capsule has not occurred require operation. From a consideration of the final results of treatment by apparatus, as well as of the pathological conditions present in this affection, we can arrive at no conclusion other than the advisability of operative interference. The period between the receipt of the injury and the operation depends, to a great extent, upon the amount of coincident traumatism and synovitis. This period varies from five to fourteen days. If there is but slight injury to the surrounding structures, and their vitality be comparatively unimpaired, immediate interference may be instituted. If the traumatism and synovitis is marked, it is best to wait a few days. In cases in which the distention of the joint is extreme, or in which there does not appear to be any attempt on the part of nature to cause an absorption of the fluid, the joint may be aspirated. The writer then gives a detailed description of the technic of his operation. He uses two knives, one for the skin and the other for the deeper dissection; also two sets of retractors. Stick-sponges are used. He never allows any hand, however well disinfected, to touch the wound. So there is no medium by which infection can enter the wound except through the air, the skin of the patient, and the suture material.

Philadelphia Medical Journal, March 28, 1903.

Mouth Infection, Due to Natural Teeth.—D. D. Smith believes that mouth infection due to teeth begins with the eruption of the deciduous set, and continues with increasing gravity through the period of shedding the temporary and erupting of the permanent ones, and thence on, so long as the natural teeth remain in the mouth. The most critical time is that of childhood and early youth. The infection in sputum, letters, telephone receivers, on lips, in beards, etc., is largely due to septic conditions of the natural teeth, and to the stagnant toxins ever present in the oral cavity.

The Use of the Electrothermic Angiotribe in Lieu of the Employment of Ligatures in the Open Operation for the Relief of Varicocele.—Orville Horwitz states that the use of the electrothermic angiotribe in the open operation for varicocele would appear to be an ideal method of dealing with conditions of the kind, removing, as it does, the only objection that can be urged against the open operation—that is, the occasional infecting of the ligature. The advantages of this instrument over the simple angiotribe appear to be: (1) The substitution of a more scientific, less crude, and less dangerous method than that depending on violent traumatism, so as to produce hæmostasis. (2) There is less danger of secondary hemorrhage. (3) There is less danger from thrombus. (4) Operation is not followed by pain. (5) The use of the electrothermic instrument is not conducive to the production of orchitis, a condition commonly attending operations in the vicinity of the cord.

Additional Notes on Organacidia Gastrica.—Mark I. Knapp declares that organacidia gastrica is a disease *sui generis*, not a symptom, having for its cause pathologico-chemical conditions, which consist in the abnormal presence within the stomach of organic, volatile, acrid acids. The persistence of this condition causes after a time the pathological condition to advance to the degree of anatomatical evidence, both microscopical and macroscopical. This disease has distinct symptoms, and may be successfully treated. The cause is not abstract. This affection always means either absolute or relative hypochlorhydria. It may be due either to the ingestion of a large quantity of organic acids, found in various foods, as pickles, salads, sauces, or the acids may have formed in the stomach. In the latter case they owe their presence either to mold growth, or to budding, sporulating, multiplying yeast, yeast growth, zymosia gastrica, as the growth of both, molds and yeast, is accompanied with the development of organic acids. The most marked symptoms are: Pain or cramps in the stomach, and gnawing sensation in the stomach, heartburn, fulness, mostly sour eructation or vomiting, dryness in the throat, thirst, headache (frontal or supraorbital), pain, or rawness behind and along the sternum and between the shoulder blades.

American Medicine, March 28, 1903.

Tetanus Cured Apparently by Antitetanic Serum.—J. R. Care reports this case. The patient had stepped on a nail in the yard and it penetrated her foot. Tetanus developed. The wound was opened, cleaned, and packed. Antitetanic serum was then administered, and internal medication of potas. bromid., tinct. hyoscyamus, tinct. gelsemium and sarsaparilla was given. Several injections of the serum were given and she became completely cured. When the serum was omitted the symptoms became aggravated until sufficient serum had been given to neutralize the toxins in her system.

The Psychic Nature of Some Disturbances of the Acts of Urination and Defecation.—Charles J. Aldrich recounts a number of interesting cases of this nature. In one case he cites ingrained modesty as the origin of this not uncommon inability to harmonize the various complex reflexes associated in the act of normal micturition. In another, who was unable to use a public urinal, the idea that it was a fear of contamination which prevented a correlation of the reflexes sufficient to accomplish the act was proved to be correct. Other cases are markedly suggestive of those peculiar obsessional ideas and actions which at times possess the psychopath.

Postpartum Subinvolution.—James E. King says that the changes that are found in the uterus are those of enlargement. The size of the organ varies from a uterus that may be felt above the symphysis to one that can be discovered only by the sound. The condition is due to the failure of the individual muscle fibers to retract and become smaller. Inflammation is present only as a secondary process. The diagnosis is not specially difficult. Prophylaxis and treatment mean attention to the prevention and treatment of those conditions which act as causative factors. Of all causes local ones are the most frequent. Laceration of the cervix is doubtless a common cause. Retrodisplacement must be prevented. Improvement in the care of women during confinement has resulted in the decrease of a vast amount of suffering.

The Lancet, March 21, 1903.

Angina Pectoris: A Criticism and a Hypothesis.—E. H. Colbeck does not find in any of the theories of the causation of angina pectoris a logical explanation of the clinical aspects of the disease. He ascribes the pain of the seizures to localized distension and stretching of the ventricular wall. As long as the heart is acting quietly, the areas of degenerated muscular tissue are able, even with a relatively insufficient blood-supply, to take their share in resisting and overcoming the intracardiac pressure during systole. So soon, however, as the work of the heart is increased, as, for instance, by exertion, emotion, etc., the area or areas of degenerated muscular wall are at a double disadvantage, inasmuch as the diseased and partially occluded coronary vessels are unable to satisfy the increased demand for blood to the territories or patches of deteriorated muscular tissue. The areas of degenerated ventricular wall are thus unable to take their proper share in resisting the increased intracardiac pressure, and in consequence undergo more or less distension and stretching. Herein lies the explanation of the pain experienced during the anginal seizure, since the affected portions of the ventricular wall contain nervous tissue in an unduly impressionable and irritable condition, which must be subjected to a considerable degree of stretching and tension. In other words, the hypothesis ascribes the pain experienced in the anginal paroxysm to localized distension and stretching of the ventricular wall.

Conditions Modifying Exanthematous Eruptions.—J. Reid notes that there is often a temptation to diagnosticate a recrudescence of a previous attack, or even a fresh zymotic disease, on the appearance of a fresh eruption, while probably sight is lost of certain factors in connection with such cases—namely: (1) the fact that the skin has passed through an inflammatory stage and is on that account a *pars minoris resistentiæ;* (2) that the zymotic disease may have attacked a constitution weakened by rheumatism or gout, where rashes often appear; and (3) that some local mischief may favor, or rather tend to induce, eruptions. As illustrating the above facts, he narrates the histories of three cases: Case 1 was that of a girl of nine years, of a rheumatic diathesis; suffered from a burn on the leg; bronchial catarrh and herpes facialis, followed by varicella, the latter followed by lichen urticatus and general desquamation. Case 2, a boy of twelve years, passed a tapeworm; measles one week later, rheumatic diathesis present; rash disappeared on sixth day, but was followed by erythema morbilliforme. Case 3, a boy of eleven months, suffered from proctitis with rectal prolapse and left-sided bubonocele; later, pneumonia, then measles. The measles lasted for six days and then pneumonia returned in the left base. A speedy desquamation followed. An erythema of one day's duration came on, and finally herpes over the left groin and left buttock, as well as near the anus and on the anterior third of the

penis. The prepuce was inflamed and required treatment. Further symptoms were gastrointestinal catarrh with green clayey motions and protracted convalescence joined to slight bronchitis; although the child rapidly put on flesh and improved in every way.

The Height of the Diaphragm in Relation to the Position of Certain Abdominal Viscera.—Nine cases were studied by C. T. Andrew, who notes the great variation, especially in female subjects, in the height of the diaphragm. In seven women the height of the dome in the right mammary line varied from the fourth rib to the sixth interspace, whereas in the two males it did not extend lower down than the fifth rib. Secondly, it is remarkable that so many abnormalities in the position of the viscera should have existed in such a small number of subjects, and that these should have existed chiefly in females; for in the seven cases examined there were two distinct and two indistinct cases of Riedel's lobe of the liver, two cases of gallstones and two affections of the gall-bladder, and one abnormality of the stomach. Both cases of Riedel's lobe were accompanied by gallstones, and in one of the cases there was an abscess of the liver and gall-bladder, while in the other the gall-bladder was greatly dilated and lay partly in the iliac fossa. Again, the measurements of the recti muscles as an indication of the strength of the abdominal muscles are interesting, as in every case they are much smaller in the females than in the males. The thickness is especially diminished in the two cases in which a Riedel's lobe is present, the recti in these cases being so thin as to feel almost like a piece of brown paper. The distance of the great curvature of the stomach and the transverse colon below the xiphoid cartilage was also greater in the females than in the males. In the case in which the diaphragm reached the sixth interspace the great curvature was seven inches below the xiphoid cartilage and the transverse colon was two inches above the pubes.

Some Points in the Anatomy and Pathology of the Vermiform Appendix.—Among the points discussed by W. McAdam Eccles in the third Hunterian lecture is that of hernia of the appendix. In such cases the question which first arises is, how does the appendix come to enter a peritoneal pouch protruded beyond the abdominal wall? The normal appendix, some three or four inches in length, with a complete mesoappendix, is free to move within the abdomen within a certain range around its attachment to the cæcum, but it cannot be brought down to, much less forced or dragged through, either the right inguinal or right femoral ring. One of two conditions, then, is necessary for its descent. In the first place it may be considerably in excess of its usual length. This can be either the outcome of congenital elongation or of a stretching the result of adhesion. In the second place the cæcum may be abnormally free because of the presence of a long mesocæcum, with the result that the appendix may thus approach dangerously near to a hernial aperture. A further point comes up for investigation in the query whether the appendix alone can be the primary and the final contents of a hernial sac. It is undoubtedly possible for it to be extruded into the sac of a so-called congenital right inguinal hernia, for in such a case there is a naturally patent processus vaginalis into which any viscus lying near may be forced. It is certainly somewhat difficult to understand how such a small part of the alimentary tract, having so little of surface area, would be able of itself to form a sac by pressure. If we suppose that other of the abdominal contents besides the appendix have been the cause of the hernial sac, it is difficult to account for the very small pouches, and these often with narrow necks, which are found not infrequently as the coverings of prolapsed appendices. Doubtless this argument is open to the rejoinder that it is quite possible for the original multiform contents of the sac to have been reduced all but the appendix (which might alone have become adherent) and then for the mouth and neck of the sac to contract around the small structure passing through them, and beyond this it is perhaps feasible that strangulation, or, at least, some constriction of the appendix, may thereby occur. Or, again, the appendix might slip into a sac which had not previously contained it, but which had been occupied by some other viscera.

British Medical Journal, March 21, 1903.

Note on the Detection of Raw Milk and Formaldehdye.—J. E. Saul has observed a very striking reaction of raw milk, which may prove useful in the examination of sterilized or scalded milk. On treating milk with a solution of orthomethylaminophenol sulphate, and then adding hydrogen-peroxide solution, a very vivid deep-red color is produced. Milk that has been previously boiled and cooled remains uncolored, a faint pink only developing on standing. The red color is so strong and pronounced that so little as 1 per cent. of raw milk, if added to heated milk, may be detected with ease. To 9 or 10 c.cm. of milk, add 1 c.cm. of a recently prepared 1 per cent. aqueous solution of orthomethylaminophenol sulphate and then 1 drop of commercial hydrogen peroxide solution. The red color develops within 30 seconds if there is any raw milk present in the sample.

Congenital Goiter.—John T. Hewetson states that congenital goiters generally assume one of three great types: (1) Adenomatous, being perfectly encapsulated tumors, occurring in the substance of the thyroid gland, containing one or more cysts, and often masses of cartilage. (2) Parenchymatous, which is similar in all respects to the came variety seen in adults. (3) Vascular, which is probably the commonest variety, in which the acini of the tumor remains fetal in character, showing an entire absence of colloid matter. Large blood vessels and widely dilated blood sinuses are present in considerable numbers. In this type cyst formation does not appear to take place. Heredity plays a very improtant part in the etiology of congenital goiter. Many cases are born prematurely or are stillborn. Of those born living, a considerable number die soon after birth. Hitherto operative measures have met with little success.

The Goulstonian Lectures on Theories of Immunity and Their Clinical Application.—A. S. Grünbaum defines immunity as the power to resist infection. Immunity may be either congenital or acquired. The two chief theories of the present day are those of Metchnikoff and Ehrlich, respectively, while the former and his school believe that the white cells directly attack the invading bacteria. Ehrlich and his followers have laid more stress on the constituents of the body fluids. Infection may be due chiefly either to the microorganism or its products. Consequently there are the two classes—a bactericidal and an antitoxic immunity. Immunity is variable in duration. It may be slight or nearly absolute; it may be individual or racial. The real starting point of Ehrlich's side-chain theory was his laborious investigation for the standardization of diphtheria toxin. Ehrlich expanded his hypothesis and applied it to explain also the normal processes of food assimilation The formation of antidotes to normal foodstuffs is quite analogous to the formation of antitoxins to toxins, so that the generation of antitoxins "is only a reproduction of a process in normal cell-life." Ehrlich believes that the proteid molecule of a food becomes attached to one group of the cell reception while the other group is already occupied by a ferment (the complement) molecule to make the foodstuff assimilable.

Deutsche medicinische Wochenschrift, March 5, 1903.

Antitoxin Treatment of Tetanus.—v. Schuckmann reports a case which was unsuccessfully treated with Behring's antitoxin. The incubation period was 10 days and the serum was first administered within 30 hours from the commencement of the symptoms. Two hundred antitoxin units were given. Death took place within 48 hours from the first appearance of the symptoms. A review of the literature shows that antitoxin is entirely without avail in those cases which show a short incubative period, even if given a short time from the first appearance of the symptoms, as advised by Behring.

Behring's Antitoxin in Tetanus.—R. A. Frotscher reports its successful use. The incubative period was 13 days and the first symptoms were mild in character. The first dose of antitoxin was given four days after the first appearance of symptoms and was 100 units. After 24 hours a second 100 units were inoculated. No marked improvement followed the inoculation, but the case proceeded gradually toward recovery. From other reported cases it is evident that antitoxin is of greatest utility in those cases which show a long period of incubation and mild and slowly developing symptoms.

Bacillus of Tetanus in the Blood.—Otto Hohlbeck reports a case of tetanus in which the bacillus was found in the blood taken from the median vein. Only three similar cases have hitherto been reported. In this case the blood was taken five hours before death. Cultures were made in bouillon. Such cultures contained both bacilli and cocci. The bacilli corresponded morphologically with the tetanus bacillus. These cultures were inoculated into eleven mice. Five of these died of typical tetanus. The bacilli, however, were not isolated from the site of inoculation in these mice. In spite of all endeavors it was not found possible to obtain the bacilli in pure culture

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON MEDICINE.

Stated Meeting, Held March 17, 1903.

LEWIS A. CONNER, M.D., CHAIRMAN.

Cirrhosis of the Liver.—The evening was devoted to a symposium on this subject.

The Pathology.—Dr. JAMES EWING discussed this part of the subject with the aid of many lantern projections of microscopic specimens.

The Anatomy of Portal Anastomoses.—Dr. ROLFE FLOYD made some remarks on this subject, basing them upon work that had been done in the laboratory of the College of Physicians and Surgeons. A dissection of the liver of the fœtus at term was exhibited with the vessels injected. He said that although in the liver at term the intralobular capillaries were present, they did not separate the portal from the systemic veins. The umbilical vein passing in from the navel crossed along the lower edge of the falciform ligament and entered the umbilical fissure. As it did so it gave off two sets of branches, one going to the right to the quadrate lobe, the other going to the left lobe. It then passed on until it reached the left end of the transverse fissure of the liver, where it terminated by dividing into three branches: (1) A large right branch going to the right lobe; (2) a similar though smaller branch going to the left lobe, and (3) a branch continuing the course of the original vessel, and passing back to inosculate with the interior vena cava. This vessel formed a direct communication between the afferent and efferent hepatic vessels. All of the branches of this umbilical vein except for the ductus venosus broke up into the capillaries which penetrated the liver lobules. At this time the portal vein was a small vessel passing up to join the right branch of the umbilical vein in the transverse fissure of the liver. Just after birth the umbilical vein from the navel to the liver became obliterated by a proliferation of its endothelial wall and by the formation and organization in its contracted lumen of a thrombus. The portal and venous systems were also made distinct. With the establishment of digestion the portal vein became enormously enlarged, and new branches of the umbilical vein appeared and were spoken of as branches of the portal canals. The hepatic veins underwent no change at this time. The speaker said he had found no record of a case of persistence of the lumen of the ductus venosus. From a study of the literature it seemed probable that in some cases at least the old channel in the round ligament was reclaimed and served as a means of portal anastomosis. Between the muscular and mucous coats of the œsophagus there was a venous plexus, which, in the lower four inches, was drained by three sets of vessels, viz.: (1) The coronary vein of the stomach; (2) small veins passing to the diaphragmatic veins, and through them to the inferior vena cava, and (3) veins known as the inferior œsophageal veins, which passed to the azygos vein. There was a plexus also connected with the rectum, consisting of the upper rectal, the middle rectal, and the inferior rectal veins. The accessory portal veins of Sappey all lay between the layers of the suspensory ligament of the liver. They comprised a superior and an anterior set. The latter constituted one of the most important sets of veins in connection with the clinical study of portal anastomosis. Sappey had called attention to the fact that in case the superficial veins became dilated they often became varicose, whereas this was not the case with the deeper ones, a fact which he had endeavored to explain by the varying angles at which these vessels entered the main trunk. In an adult, the chief means of portal anastomosis were the œsophageal veins, the rectal veins, the veins of Sappey, and the retroperitoneal veins.

The Diagnosis.—Dr. WALTER B. JAMES said that cirrhosis of the liver in the autopsy room did much to shatter one's blind faith in many of the time-honored rules of diagnosis. Only a certain proportion of the cases gave rise to pronounced symptoms of the condition. The physical signs of the disease might also be in the highest degree atypical. Enlargement of the superficial abdominal veins had always been regularly counted among the valuable indications of the disease. Often it seemed to him that too little attention had been paid clinically to the relative value of these different sets of veins. Much stress had been laid upon the presence of a set of enlarged venules around the umbilicus—the so-called caput medusæ—as a sign of hepatic cirrhosis, and while no doubt it was an important sign it had not been very often present according to his experience. Enlargement of the abdominal veins was often observed in distention of the abdomen from any cause. Ascites of the liver presented no special peculiarity, although a systematic study of the fluid might sometimes prove of assistance. A comparatively low specific gravity, a small quantity of albumin, and a paucity of cellular elements were the characteristic features of the fluid in hepatic ascites. The difficulty of palpating the moderately enlarged spleen in a person having ascites was obvious; hence this sign was not of any particular value. The accentuation of the umbilical notch was a feature of many livers which he believed was not generally appreciated. This deepening of the notch apparently occurred in many cases from a dragging upon the falciform ligament. In cases of moderate enlargement of the liver he believed that the best information regarding the size of this organ was obtained from deep percussion at the back. It should be borne in mind in making the differential diagnosis that cirrhosis of the liver was apt to be mistaken for adherent pericardium, particularly in young persons. Theoretically, cirrhosis of the liver and cancer of the liver should not be confounded, but practically this was not the case, at least in the early stages. There was a group of cases, often of long duration, in which there was anæmia of the type of simple anæmia, associated with a tendency to profuse bleeding from the stomach and marked enlargement of the spleen, with more or less ascites. In the final stage there was apt to be ascites and general anasarca. The differentiation of these cases of splenic anæmia from cirrhosis of the liver was difficult, if not impossible. In his experience biliary cirrhosis was a rare disease, which was met with usually in young persons and had no history of alcoholism. The liver was apt to be persistently enlarged, and splenic enlargement and ascites, if present at all, were generally not very prominent. Periods of fever occurred. The common clinical forms of hepatic cirrhosis met with here were the ordinary atrophic form, the fatty form, and syphilitic cirrhosis. The last-named condition he believed to be a great deal more frequent in New York City than had been supposed. In atrophic cirrhosis there were enlargement of the spleen, extensive and rapidly recurring ascites, wasting, absence of fever and jaundice, and often a history of alcoholism. In the fatty and cirrhotic form there was less marked emaciation and relatively frequent fever and jaundice. In syphilitic cirrhosis there was a history of syphilis and a very marked irregularity in the shape and surface of the liver. It occurred commonly at an earlier age than hepatic cirrhosis of the ordinary form. Cirrhosis of the liver, therefore, was to be recognized generally not by new points in diagnosis, but by the study of every possible feature of the case, and by a critical estimate of all data so obtained.

Dr. GEORGE L. PEABODY said there was still a good deal of erroneous teaching in good textbooks regarding the changes in size which the liver underwent in cirrhosis. He believed there were very few clinicians who had seen a liver which was at first enlarged grow small. It was also wrong to assert that one could usually make out the nodules on the surface of the liver in that form famil-

iarly spoken of as "hob-nail liver." He did not believe there was any way of absolutely making the diagnosis early in the disease, and there were many cases in which it was difficult to do this, even in the late stages. Ascites was, of course, a great help, but one must eliminate peritonitis of tuberculous and cancerous origin, and yet no disease perhaps more predisposed to tuberculosis than cirrhosis of the liver. A right-sided pleural effusion was sometimes a diagnostic help. The fact that hæmatemesis could occur very early in hepatic cirrhosis had been impressed upon him in his own experience, yet hæmatemesis might result from gastric ulcer or some other cause. He had met with one case of early and profuse hæmatemesis occurring without ascites or symptoms pointing to hepatic cirrhosis, and yet so severe as to terminate fatally. The differential diagnosis between hepatic cirrhosis and nutmeg liver could often be made only by close observation for some time and a full consideration of the history. He had also found hepatic cirrhosis frequent at autopsy in cases which had been carefully observed by others as well as himself without a suspicion of the existence of this condition.

Morrison's Operation.—Dr. George Woolsey said that the operation known as Morrison's was, of course, a comparatively new one, not being more than five years old. It had been suggested by the fact that advance cirrhosis was almost uniformly fatal under medical treatment, and that the portal anastomosis referred to involved chiefly the liver, the spleen, and the omentum. Some had doubted if the good effect of this operation was really due to the influence of the anastomosis upon the portal circulation. He had been in the habit of scraping the surface of the liver, spleen, and overlying peritoneum with a piece of dry gauze with the object of securing an anastomosis, but it was found that this was not always accomplished by such means. It was known that fluid effusion interfered with the formation of such anastomoses, and it was often desirable, in the presence of ascites, to strap the chest from the ensiform cartilage to the umbilicus, and to have the patient maintain the sitting posture so that the fluid would drain naturally into the lower part of the abdomen. In even the most successful cases tapping was usually required one or more times. The results of this operation had not been particularly satisfactory. Dr. Brewer had collected a number of cases about one year ago with a mortality of 33 per cent. He had himself operated upon six cases. One of these patients was living and entirely well, but four were known to have died. The other case had been lost sight of after some time. In the four fatal cases death resulted from general debility and toxæmia; there had been no death from peritonitis or sepsis. The operation could be said to be a safe one. Most of the cases first operated upon by this method had been advanced ones, which probably explained some of the bad results.

Dr. C. N. B. Camac exhibited a photograph of a typical case of Hanot's cirrhosis. The patient was thirty-six years of age, and exhibited marked jaundice and prostration, with considerable gastrointestinal disturbance. There was a complete absence of an alcoholic history. The case had been seen at the Cornell Medical School.

Dr. Andrew H. Smith spoke of the aid in differentiating the dulness of two contiguous organs, the one from the other, as, for example, the liver and spleen. This was auscultatory percussion. It would often prove very valuable, and would give a decided change in the note when passing from one organ to the other, even though no such change could be detected by ordinary percussion.

A Cholera Infantum Serum.—It is stated that the New York City Health Board officials have been preparing a serum for use in the summer diarrhœa of infants, the cause being assumed to be the Shiga bacillus.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON SURGERY.

Stated Meeting, Held March 9, 1903.

Robert T. Morris M.D., Chairman.

Racemose Arterial Angioma of Frontal Region.—Dr. Carl Beck presented several cases. The first was a man twenty-eight years of age, who seventeen years ago had been struck by a stone in the middle of the forehead. Ever since then there had been some elevation of this part, but the swelling had increased gradually until a pulsating mass of vessels was spread over the nose and forehead. When first seen by him a few weeks ago he had endeavored to control the pulsation by digital pressure, but this accomplished nothing. Six weeks ago he had attempted to control the pulsation by ligation of the temporal, frontal, and angular arteries, but as this proved of no avail he proceeded four days later to the extirpation of the tumor, using the interrupted prophylactic suture. Although the operation was rapidly done, and every effort made to control the hemorrhage, the latter was enormous, and the man was nearly pulseless at the completion of the operation. He revived under saline injections. There was no pulsation at present. Microscopical examination of the vessels threw no light upon the case.

Extensive Syphilitic Destruction of the Nose; Treatment with Paraffin Oil.—The second case was one of syphilitic destruction of the nose occurring in a woman of thirty-eight years. There was a history of the ulceration having begun three years ago. The whole nasal support and a part of the frontal bone and hard palate had been destroyed. Mixed treatment and inunctions were first used, and then the frontal sinus was exposed and drained. After a few months an osteoplastic operation was done, but was uusuccessful. By means of injections of paraffin oil her condition had been somewhat improved.

Osteosarcoma of Orbit Treated Successfully by the Röntgen Rays.—The third case was one of osteosarcoma of the frontal bone and orbit treated first by operation, and afterward by the *x*-ray. The patient was a woman of forty-two years, and the first signs of osteosarcoma of the orbit had been noticed fifteen months ago. The eye was enucleated in a neighboring town, but a very speedy recurrence ensued. When first seen by Dr. Beck there was an enormous tumor extending over the whole frontal bone. Formerly it would not have been wise to take out a part of an osteosarcoma, but with the aid of the *x*-ray this method could be adopted with advantage. The *x*-ray treatment had been timidly pursued for a time, but as there was evidence of recurrence the treatment was pushed with stronger currents, and this had resulted in decided improvement.

Congenital Nævus Formation of Oral Cavity.—Dr. Frederic Griffith presented a young woman having a congenital nævus formation on the right side of the oral cavity. When the mouth was open the tumor lay between the teeth, but was never caught in them. Numerous silk sutures were passed through the base of the growth under cocaine anæsthesia, and the tumor was extirpated. Bleeding was free, but was readily controlled by tying the sutures consecutively. According to the literature, such growths on the mucous membrane were uncommon.

Gangrene Following Operation on X-Ray Cases.—Dr. Samuel Lloyd said with regard to the case of osteosarcoma that we should now revise some of the claims made a year ago concerning the *x*-ray treatment. Even the most enthusiastic *x*-ray workers had now recognized that such treatment did not seem to influence favorably the deeper growths He had seen two cases of epithelioma in which the proliferation had gone on very much more rapidly since beginning the *x*-ray treatment, although the latter had been thoroughly carried out by experts. He had recently operated upon two cases that had been subjected to *x*-ray treatment for a considerable

time. In one there had been no *x*-ray treatment for some weeks prior to operation; in the other case the *x*-ray treatment had been continued up to the time of operation. In the latter case, although the parts were brought together without tension, a gangrenous patch developed,and nearly covered the whole area that had been exposed to the *x*-ray. At the time he had not attached very much importance to this, believing that it was due to some fault in the technique, but when he had subsequently observed a second case of the kind he had been led to ponder over the significance of the observation. The case was one of carcinoma of the breast, and while he obtained easily an abundant flap there developed subsequently a gangrenous patch covering the whole side of the chest. He was inclined to think that in both instances the *x*-ray had produced an unfavorable change in the nutrition of the tissues. If further experience proved this to be true, it would suggest the advisability of avoiding *x*-ray treatment until after operation. He was willing to admit that wonderful results sometimes followed the use of the *x*-ray in superficial eptiheliomata too far advanced for the usual operative treatment. In cases in which there were superficial recurrences of carcinoma of the breast the *x*-ray treatment was also beneficial.

Dr. E. M. Foote said that he had operated upon a case of recurrent carcinoma of the breast that had been exposed to the *x*-ray eighteen times. There was a superficial burn along the line of the original scar. The burn was neither very large nor deep. The whole burned area was removed at the operation, and the skin was sutured without very much tension, yet, a few days after the operation, although there was no gaping of the suture line, a patch of superficial necrosis developed, and extended apparently as far as the *x*-ray had gone.

The Lesion in a Severe X-Ray Burn.—Dr. James P. Tuttle referred to a case in which he had been compelled to amputate the thigh because of the results of an *x*-ray burn. That was the only case in which a careful pathological and microscopical study of an *x*-ray burn had been made After the amputation a very close study of the parts around this burn had been made by the late Dr. William Vissman. His conclusion was that the *x*-ray burn was the result of the production of an endarteritis and a periarteritis. The alteration in the capillary supply about the burn seemed to explain the failure to secure healing. This observation might explain the gangrene referred to by the previous speakers In his own case the endarteritis had extended three or four inches outside of the actual burn or slough, showing that the effect upon the arteries was not confined to the part which sloughed as a result of the burn.

Epithelioma Engrafted on X-Ray Burn.—Dr. Lloyd said that at one time he had worked in Edison's laboratory with the *x*-ray. The tube-maker there received very severe burns on his hands and head. Finally he lost all of the skin on his hands. He was skin-grafted in two or three hospitals, and finally returned to New York with an epithelioma developed on the *x*-ray burn of the right hand. This epithelioma grew rapidly while he was under *x*-ray treatment, and eventually Dr. Lloyd had been compelled to perform amputation.

Sarcoma of the Antrum of Highmore; Operation.—Dr. Charles A. Elsberg presented a boy of eleven years, who had come to him at the Mount Sinai Hospital with a slowly growing tumor in the region of the right superior maxilla. The tumor had gradually appeared on the cheek, had caused bulging of the orbit, and had grown into the nasal fossa and mouth. There were some enlarged glands in the neck on that side. A portion of the tumor was removed from the mouth for examination, and the pathologist reported it to be a myxosarcoma. Dr. Elsberg tried the external carotid artery prophylactically to control hemorrhage, and removed half a dozen small glands of the neck on that side. He then exposed the tumor by the Dieffenback incision as modified by Kocher, and the tumor was found to have originated in the antrum of Highmore. A very extensive operation was required for the removal of the growth. The case was presented partly because there was no drooping of the eye. This was because a slip of the temporal muscle had been thrown underneath the eyeball so as to form a sling upon which the eyeball might rest. Another reason for showing the case was the extensive new formation of bone. There was only a slight sinking in of the malar region, and this would be rectified by paraffin injections.

Removal of Sternum and Reproduction of Bone—Dr. Elsberg also presented a man, twenty-seven years of age, upon whom he had operated about a year ago for extensive tuberculosis of the ribs. He had previously been operated upon by others a number of times, and there were several sinuses leading down to bare bone in all directions. There were signs of slight tuberculous disease in the lungs. The entire sternum and four ribs were completely removed about two inches from the sternum. As the periosteum was largely sacrificed it had been a question how much reproduction of bone would take place. For some time after the operation the heart could be felt beating under the finger applied to the front of the chest in the sternal region. The case was presented because there had been reproduction of bone all over the area operated upon.

Dr. Lloyd said he had just seen a patient with diabetic gangrene of the foot upon whom he had operated for sarcoma of the sternum nearly fifteen years ago. All of the sternum except a small portion at the sternoclavicular articulation had been removed, yet at the present time it was completely filled up with new bone.

Dr. Beck opposed the plan of subjecting cases to *x*-ray treatment before operation; such treatment should be reserved for after-operation, or that part which could not be done with the scalpel There could be no question about the potency of the *x*-ray, but we must learn how to control this new therapeutic agent. It was probable that the destruction of the blood vessels would vary with different growths.

Office Treatment of Diseases of the Rectum.—Dr. Samuel G. Gant read this paper. He found it difficult to understand why so many of these cases were treated in hospital which could be effectively treated with less sacrifice and discomfort in the physician's office. On the morning of the day preceding treatment or operation three ounces of carabana, or other laxative water, should be taken, and three hours before coming to the office the bowel should be washed out, and as a final preparation a small glycerin and water enema should be taken. Much unnecessary pain could often be avoided by the use of the injection of a three-per-cent. solution of beta eucaine or a four-per-cent. solution of cocaine. His own preference was for the former.

Hemorrhoids.—In the operative treatment of external hemorrhoids the tumors should be injected with a three-per cent. eucaine solution, transfixed with a bistoury, laid open and packed with a narrow strip of gauze for twenty-four hours. External cutaneous hemorrhoids should be excised with the scissors or by means of an elliptical incision, the wound being allowed to heal by granulation. The parts should be cleansed with warm water daily. Small, flat internal capillary hemorrhoids, which bled freely, should be treated by applying the galvanocautery or carbolic acid. The intervals between the cauterizations should be at least a week. Non-protruding internal venous hemorrhoids could often be cured by the injection of a solution containing carbolic acid. To obtain the best results from this method and avoid its dangers, it was essential to observe asepsis, inject the solution into the tumor and not into the deeper structures, and place the finger over the puncture to prevent the escape of the solution into the bowel. He had long used with satisfaction an injection fluid composed of one drachm each of carbolic acid, glycerin, and distilled water prepared freshly for each

treatment. From five to fifteen drops were injected into small, and ten to thirty drops into large piles. Should the inflammation become intense or sloughing occur, hot or cold applications would be required, and suppositories of opium or belladonna to relieve the pain. Two ounces of carabana water should be taken each morning.

Polypi.—For polypi or mild cases of prolapse it was very easy to apply the little clamps which he had devised, and which were left on until they produced pressure necrosis and came away with the fæces.

Ischiorectal Abscess.—Ischiorectal abscess must be treated radically to prevent the formation of a fistula. If the skin were tense over the abscess, anæsthetization could be effected by freezing, but for deeper accumulations of pus eucain injections were required. These abscesses must always be opened by a free incision.

Fistula in Ano.—Cases of fistula in ano could be treated painlessly by the injection of eucaine solution into the skin over the sinus and into the muscle. Complete division should be effected on a grooved director, and a suppository containing one-fourth of a grain each of morphine and cocaine inserted into the bowel. The ligature operation for fistula was occasionally justifiable in depleted subjects because it avoided loss of blood. An elastic ligature should be carried up through the sinus and down through the anus by means of a probe, and the ligature secured with shot. The ligature would cut through in about ten days after the treatment, with the same result as after complete division. The injection method was only serviceable in very recent fistulæ. The latter should be irrigated and then injected with a strong solution of zinc, ergotin, ichthyol, carbolic acid, or iodine. This injection should be repeated at intervals of two or three days.

Fissure of the Anus.—A recent fissure of the anus could frequently be cured by daily cleansing of the ulcer and by the application of ichthyol, nitrate of silver, or balsam of Peru. Complete division of the sphincter was the most certain method of relieving fissure. The operation could be quickly performed in the office. After the muscle and skin had been anæsthetized by a eucaine injection, a probe-pointed bistoury was guided into the rectum and directed backward, and the muscle then divided. Healing took place rapidly under balsam of Peru dressings, and the patient could continue at his business. Extensive ulcerations high up in the rectum or in the sigmoid flexure should be treated by spraying the bowel with weak astringent solutions, or by irrigation with a weak solution of nitrate of silver.

Catarrhal Inflammation.—Catarrhal inflammations of the colon and rectum could usually be satisfactorily treated in the office. In acute inflammation the patient should rest as much as possible, abstain from cold carbonated or alcoholic drinks, and use only light liquid nourishment. In chronic proctitis the local applications should be stronger. On alternate days the colon should be irrigated with a solution of nitrate of silver of the strength of thirty grains to the pint, and followed by normal saline solution. On the intervening days an emulsion of bismuth, one drachm, with some iodoform and four ounces of olive oil should be injected and retained. It would be found very soothing.

Constipation.—He believed that nearly all cases of constipation could be materially relieved or cured by office treatment. When necessary, the sphincter could be divided or divulsed. In some cases division of the rectal valves was necessary. The regulation of the patient's habits of life was, of course, very important.

Dr. James P. Tuttle said that the advisability of employing office treatment for rectal diseases was an open question, and the physician who would be successful in such work must be a good judge of the character of his patient. The patients desiring this slow treatment were almost always men. The author of the paper well knew that the quickest and most satisfactory method of curing hemorrhoids was by etherizing the patient and doing a thorough operation. The injection treatment of hemorrhoids was not absolutely reliable and radical, and it was apt to be followed by recurrence. The advertising specialists who treated fistula "without operation" really made a slight incision under cocaine at each sitting, and eventually succeeded in curing the fistula. The great danger from the office treatment of these cases was hemorrhage. The eucaine or cocaine contracted the blood vessels, and there was very little oozing during the operation, but by the time the patient had reached home the dressing was disarranged, and the effect of the cocaine having passed off, the bleeding was apt to be profuse. He did not think it was either necessary or expedient to take such chances. All the desired anæsthetization could be obtained from a one per cent., a half per cent., or even a quarter per cent., solution of cocaine injected hypodermically. However, the absorption of the drug when injected free into the bowel was often so great and rapid as to lead to disastrous consequences. When a fissure of the anus was situated in the anterior or posterior commissure it was very slightly influenced by incision or divulsion of the sphincter. In such cases a V-shaped incision should be made on either side, not over half an inch deep, and then the fissure scraped or any fibrous tissue dissected out. He was utterly opposed to the local application of nitrate of silver to fissures of the rectum, because it always produced a deposit of fibrous material, thus forming a hard cicatrix which was often more painful than the original fissure. He had frequently had to dissect out these deposits. The use of ichthyol was far more beneficial.

Ichthyol for Anal Fissure.—Dr. A. Ernest Gallant said that some years ago he had experimented with the use of pure ichthyol in the vagina and in fissures of the anus, and it had acted so rapidly that he saw no reason for using weaker solutions. It rarely required more than three applications of the pure ichthyol to effect a cure, and if very painful some relief would be afforded by the application of cocaine. The ichthyol was not nearly so effective when mixed with glycerin. He had always opposed the use of nitrate of silver because of the induration it produced.

Injection Treatment of Hemorrhoids a Failure.—Dr. Joseph Wiener said that he felt sure that many of those who employed the injection treatment of hemorrhoids did not know the ultimate results of such treatment, or else it would be less freely employed. There was a field for the injection treatment, but it was an extremely limited one. As a rule, surgeons did not see cases of hemorrhoids which could be *cured* by the injection treatment. Mention was made of a case of hemorrhoids which had received an injection and, two or three days later, as a result of sloughing, developed a hemorrhage which very nearly proved fatal. Other cases were cited to show that most patients did not return to the one who had given the injection treatment, and that those employing this treatment were consequently led to believe that they had effected cures when this was far from the truth.

Dr. Robert T. Morris remarked that he had seen two cases of gangrene of the lung which had developed after the injection treatment of hemorrhoids.

Dr. Gant closed the discussion. He said that he had not earnestly advocated the injection treatment of hemorrhoids, and, indeed, he thought there were few rectal specialists who used it less than he. He would not think of injecting a strangulated hemorrhoid, or one which was very œdematous or highly inflamed, nor would he inject an external hemorrhoid. If, however, a patient would not consent to a better operation he would inject small hemorrhoids which bled freely and which, as a rule, remained above the sphincter, although perhaps coming down occasionally. He made it a point not to claim that the injection would *cure* hemorrhoids, and he was careful to explain this to his patients. However, it did not follow that the injection method was the only one which was followed by a return of the hemorrhoid, for,

he had seen this occur after a Whitehead operation done by a competent surgeon. It was perfectly possible to thoroughly anæsthetize the hemorrhoid by the injection of cocaine or eucaine; then make a shallow incision around the hemorrhoid and ligate the latter without causing the patient pain. Before injecting the pile finally with cocaine or eucaine a suppository containing a quarter of a grain each of cocaine and morphine should be introduced into the rectum, and this would save the patient from severe pain that would recur as soon as the effect of the cocaine or eucaine had passed off. It was very important not to overlook this point. It was true that there was some danger of hemorrhage, but a good deal of annoyance could be avoided by packing with adrenalin chloride. A good deal depended also upon the use of a proper T-bandage, one having a belt at least six inches wide and broad tails. He had been interested in the point made by Dr. Tuttle regarding fissures situated in the anterior or posterior commissures, but his experience had taught him that the fibers of the sphincter ani crossed over as well as simply decussated laterally. He had never failed to cure a fissure by division. The simple cutting of the sphincter was not sufficient, because it did not give drainage; but with a free incision of the skin also, and proper packing, a cure would result. In the treatment of rectal diseases the most essential point was drainage. He had used a three-per-cent. solution of eucaine very freely in rectal surgery, and had never seen any ill effect from it, whereas he had observed many bad symptoms from the use of cocaine. According to his experience, the mild solutions of nitrate of silver did not give rise to the indurated conditions referred to in the discussion. He thought the milder solutions of ichthyol accomplished as much as the pure ichthyol, and he preferred them because they caused less pain. It was quite important not only to make the application to the fissure, but to leave the cotton pledget *in situ*.

A Preliminary Report on Some Experiments with the McGraw Elastic Ligature.—Dr. M. S. Kakels presented this paper. He exhibited one of these ligatures which he had recovered, and commented upon its insignificant size as compared with the Murphy button. The chief advantages claimed for the operation by McGraw were: (1) It was the simplest of all known methods; (2) it was the quickest of all operations for intestinal anastomosis; (3) there was uniform coaptation of the peritoneal surface of the entire circumference of the proximal ends; (4) there was no incision of the bowel and no blood was lost; (5) there was no escape of fæces and no exposure to infection from the bowel contents; (6) the operation was followed by a minimum of shock; (7) the anastomosis was secured by first intention; (8) very few lesions were made, and (9) the bowel did not slough under the ligature. Dr. Kakels said he had made a number of experiments upon dogs, and had subsequently killed the animals at varying intervals by the administration of cyanide of potash. His conclusions from these experiments bore out in the main the claims made for the operation by its originator. He found the operation fully as simple as the one with the Murphy button. Of the eight experimental cases in only two was there partial cutting through of the ligature. This was probably to be explained by the peculiar anatomical conditions found in the bowel of the dog. The larger ligatures cut through more quickly because more tension could be applied to them than to the smaller ligatures. The specimens from these dogs were exhibited.

Dr. S. Lloyd said that he had done the McGraw operation seven times without a death, all but one of the cases being cancer. He had found it the quickest of all the operations devised for this purpose. What appeared to be a weak point in McGraw's technique was the tying of the ligature. The latter could be held just as firmly by using a stronger silk ligature and tying the ends of the latter down upon the rubber ligature. He had also found that there was no harm from beginning to feed the patients as early as forty-eight hours after the operation. One of his patients had died about three months later after a secondary operation, done in Montreal, and the autopsy had shown the opening present but strictured by a recurrence of the carcinoma.

Dr. Elsberg said that he had done two gastroenterostomies with the McGraw ligature, and had been greatly impressed with the simplicity and rapidity of the operation. He had noted the great prominence of the knot when the McGraw technique was adopted, and had, in his second operation, adopted the method of fastening described by Dr. Lloyd. Very much depended upon the tension placed upon the ligature, for, unless the two loops were approximated very closely and sufficient tension were made the time of cutting through would be lengthened.

Dr. Arnold Sturmdorf said he had assisted Dr. Kakels in his experimental work, and he thought Dr. Kakels was entitled to much credit for the pains taken to throw light upon this operation. The speaker said he had done one of the gastroenterostomies on the dog, and wished to say that in attempting to tie the ligature it had slipped from his hands and had cut an opening of considerable size in the bowel. This was an accident which might happen to any one, and should be borne in mind when operating upon the human being. McGraw was right in his contention that the ultimate anastomosis was established by absorption and not by the cutting through of the ligature. Again, it should be noted that the ultimate openings were not as large as had been expected by those who had been present at the operations.

Dr. Fred Kammerer said that for the past six or eight years he had done exclusively the posterior gastroenterostomy with the Murphy button. He thought if the incision were made into the stomach and the intestine, the two halves of the button introduced, and then, without a purse-string suture, they were brought together after closing the superfluous opening with one or two sutures, an excellent approximation of the peritoneal surfaces would be obtained. This could not be obtained if the purse-string suture were used. In no instance had he failed to do a rapid and a successful operation. He had had no personal experience with the McGraw ligature.

Dr. Kakels thought the knot used by McGraw was an advantage, as it held the parts in better apposition than if the ligature were tied with silk. There was no harm in the knot; it made a very small foreign body afterward, as was shown by the McGraw ligature which had been recovered in one case.

The "Giornale Medico Del Regio Esercito" celebrates the fiftieth anniversary of its existence. It was founded in 1851, but was obliged to suspend publication for a year and a half at the time of the Crimean war. It was at first issued as the *Journal of Military Medicine of the Sanitary Commission of the Sardinian Army*, but the word Italian was substituted for Sardinian in 1861. In 1885 the title became *Medical Journal of the Royal Army and Navy*. Up to that time the Sanitary Commission of the Army and Navy had been one, so that the journal was in truth the organ of both branches of the service, but after the separation of the Commission into two bodies, the magazine gradually lost this position. With the object of resuming it, the new title was taken. In 1895 so great had been the growth of the Navy that it was deemed best to start another journal devoted to its interests, and thus was born the *Annali di Medicina Navale*, which is so excellent a publication that the editors of the *Giornale del Regio Esercito* congratulate themselves on having been, in a sense, its originators. As to their own journal they hope that in fifty years more it will be able to record even greater usefulness than in the past.

THE MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, Held March 23, 1903.

CHARLES N. DOWD, M.D., PRESIDENT.

Immediate Perineorrhaphy.—Dr. J. MILTON MABBOTT presented this paper. He said that when the laceration was chiefly in the vagina the temptation was very strong in private practice to allow it to pass unnoticed. The method of bandaging the limbs together, though shiftless and inefficient, yielded results that compared favorably with those frequently obtained by suturing when done by careless or inexperienced hands. The perineum should be repaired whenever possible immediately after delivery, but equally good results might be obtained any time within the first twenty-four hours. Continuous and buried sutures did not appeal to him, and strange and ingenious methods of suturing had always been reserved for the secondary operation. His plan was to make use of deeply inserted interrupted sutures placed about half an inch apart. A finger in the rectum would prevent that viscus from being injured. It was usually better to introduce the highest suture in the vagina first, and work from above downward, tying the sutures in the same order. Sterile catgut was the best material for use within the vagina, as it did not require removal, and as firm union was expected in a week the larger sizes of catgut, No. 2 or No. 3, would answer for this purpose. When necessary, instead of introducing the suture with a single sweep, the needle could be brought out at the deepest part of the wound and reinserted. To secure proper coaptation each suture should be so introduced as to be elliptical, with its long axis transverse. The more deeply the needle was carried toward the sides of the pelvis in a circular sweep the more tissue would be included and the better would be the coaptation. Such a suture could be easily inserted by means of a strong straight needle, one inch and a half to two inches long, having a very slight curve near the point, and held in a strong needle-holder. Inexperienced operators were fond of the full-curved needle, yet he considered this an abomination, the straight needle yielding far better results. The sutures should not be drawn too tightly, although some allowance must be made for swelling. Technical knowledge of the finer points of anatomy were not required for the successful performance of the immediate operation of perineorrhaphy. Where assistants were scarce, the knees could be tied up by means of a sheet passed around the neck and shoulders of the patient. He did not like to give chloroform after labor, because of the danger of hemorrhage, and the administration of ether was troublesome. The bowels should be evacuated on the second or third day, and the patient could be allowed out of bed on the tenth or thirteenth day, as in cases in which no such operation had been done. Except in cases of complete rupture the perineum should give no anxiety after the operation had been done as just described.

Application of Hospital Methods for the Prevention and Treatment of Puerperal Sepsis to Private Practice.—Dr. WILLIAM S. STONE read a paper with this title. He said that the statistics of the New York City Health Department for the past two years showed that during this period there had been 178,139 births, including stillbirths, and that 1,290 women had died from the complications of childbirth. Of this number 494 were reported to have died of puerperal infection. The purpose of this paper was to emphasize the fact that the essential parts of obstetric practice were based upon a few bacteriological examinations and a few methods of procedure, which were as completely applicable to the humblest home as to the well-equipped modern lying-in hospital. Asepsis instead of antisepsis was the underlying principle. No antepartum douches should be used, except when there was a mucopurulent discharge, and then to protect the baby's eyes. The patient's external genitals, the attendants' hands, and the dressings should be carefully sterilized. No postpartum antiseptic douches should be used unless for special indications. As few examinations should be made as possible, and in each instance the hands and the patient's genitals should be thoroughly sterilized. The patient should be delivered on the side. Freshly-laundered towels, especially if wrung out of bichloride solution, would serve as good substitutes for sterilized towels. It was doubtful if the application of antiseptic solutions to the genitals really fulfilled the theoretical indications, because of the brief period of contact. The author said he had used rubber gloves in his obstetric practice for the past two years, and the improvement in the temperature records seemed to point to the value of such gloves. It seemed to him that they were especially applicable to those engaged in general practice, and consequently exposed to many sources of infection. It should be borne in mind that, in the overwhelming majority of cases, fever during the puerperium pointed to sepsis. The majority of the cases showing fever at the end of the first week, or later, were examples of septic intoxication, and in these cases recovery almost always occurred. From 70 to 80 per cent. of true septicæmia or pyæmia would recover; the most fatal cases were those in which the symptoms began very soon after labor. The fever was by no means such a good indication of the severity of the infection as was the pulse, and recovery often took place after very high elevations of temperature. As soon as fever appeared, the breasts and constipation should be excluded. This having been done, the patient should be transferred to a table and placed in the lithotomy position. After sterilization of the hands and external genitals a systematic examination should be made, beginning at the perineum. A very common error in the treatment of a patient presumably septic was to give an intrauterine douche without a previous examination of the perineum, vagina, and cervix. In this way a transference of the septic matter from the lower part of the birth canal to the uterus often resulted. A grayish slough was a sure sign of infection. It was often unnecessary to go further than the cervix to discover the cause of the fever. If the uterus appeared to be the offending part, internal palpation should be made with one or two sterile fingers, aided by firm pressure from above. If the uterus appeared to be the source of the sepsis, it was a good plan to have a bacteriological examination made of the secretions taken from the interior of the uterus. The normally roughened placental site was apt to be mistaken by the inexperienced exploring finger for retention of the products of conception. The author protested against the use of antiseptic douches, either continual or at frequent intervals, in this class of cases. Ergot administered at rather frequent intervals was a much more certain aid in maintaining good uterine contraction. If pelvic cellulitis or peritonitis were present, an ice-bag should be applied over the abdomen. A rapidly spreading peritonitis might possibly indicate such radical measures as hysterectomy, but the difficulties of making an accurate differentiation of the class of cases in which this was demanded were obviously very great. Finally, it should be noted that there was no good ground for the belief that any specific medication was efficient in the treatment of puerperal sepsis.

The Management of Posterior-occipital Positions.—Dr. JAMES D. VOORHES was the author of this paper. He said that those who examined only in the second stage of labor would find a much smaller number of posterior positions than those who examined at the beginning of labor. The records of the Sloane Maternity Hospital showed that, of 1,000 vertex cases, 194, or about 20 per cent., were primarily occipito-posterior positions. He was

positive that left occipital posterior positions were much more frequent than was generally supposed. In his private practice the first 100 cases yielded 27 per cent. of cases in which the position was right occipital posterior and 7 per cent. in which it was left occipital posterior. Of prophylactic measures for the management of occipitoposterior positions, postural treatment or external manipulations at the beginning of labor could be tried, though it was doubtful as to how much success would attend these efforts. Small doses of quinine and strychnine, used for two or three weeks before labor, he believed to be of value in preventing such positions. It should be remembered that a rather large proportion of the posterior cases rotated anteriorly before delivery. One of the most important factors in securing this rotation was the presence of powerful uterine contractions. When the pelvis was normal one should endeavor to secure as full dilatation of the cervix as possible; then, under anæsthesia, carry the hand into the uterus and rotate the child anteriorly. Then, with the head held in position by the hand inside of the uterus, and aided by an assistant's making strong pressure on the fundus, the forceps should be applied to the sides of the head. Rotation of the head by means of the forceps above the brim, using force, was fraught with great danger to the mother, and often resulted in failure. If the head did not descend under moderate traction, version would be found better. The most trying cases were those of dry labor, with contraction of the uterus about the child. Here, the blades did not fit the head and the hold was insecure. It was necessary to make strong compression, and this often resulted in intracranial injury. In another group of cases the head was engaged at the superior strait. Sometimes manipulation which would increase the flexion would allow of descent and would favor rotation. Sometimes in cases suitable for the forceps, if both blades of the forceps were introduced posteriorly, the head would rise above the brim, and then would rotate with the blades. In a third class the head was at the pelvic outlet and the occiput posterior. This was the largest class, and in many of these cases the occiput rotated spontaneously. Out of 104 persistent occipitoposterior positions at the Sloane Maternity Hospital, 55 were allowed to be born with the occiput behind, and only in 4 was the perineum slightly torn. Nine of these were primiparæ. Of 44 cases 27 were treated successfully by manual rotation. In a few cases in which the head was wedged in the pelvis, and other methods failed, the blades should be introduced in the usual manner and applied to the sides of the child's head. Then the handles of the forceps should be carried to the left thigh of the mother. By this manœuvre flexion was increased. Then, with very little force, the handles should be swung downward, describing the arc of a circle. After partial rotation the forceps could be applied for a few pains with the pelvic curve reversed. After being sure that the occiput would stay in front the blades should be removed. The force must never be great. The solid-bladed forceps was the best for this class of cases. This last method was, however, not often required.

Dr. Franklin A. Norman said he had found a distinctive advantage in using a *slightly* curved, instead of a perfectly straight, needle for perineorrhaphy. It seemed to him very important to make use of anæsthesia for perineorrhaphy, for many women suffered so keenly from the introduction of the sutures that they retained a very vivid recollection and dread of the operation. Of course, this did not apply to cases in which all of the suturing was done within the vagina. With regard to the prophylaxis of sepsis, it seemed that there was a disadvantage in the side position, because of the fact that the anus was in the immediate field of operation. For this reason he thought it was better to make use of the dorsal position, provided a firm, level bed-surface could be secured. If inspection showed a septic cervix, it should be remembered that this was generally an indication of a very septic endometrium. The endometrium and the cervix were too closely connected for the conditions to be separate. With regard to the rotation of the head by the introduction of one blade of the forceps, he thought if the blade were rotated laterally to the sides of the pelvis, while opposing pressure was made with the hand upon the child's forehead, it would often be possible to bring the head around, and then it could be held in position by the application of the left blade. This assistance rendered by the hand was of importance.

Dr. Russell Bellamy spoke in favor of the use of rubber gloves in obstetric work. With reference to intrauterine douching, he said that while on the house staff at Bellevue Hospital many cases of criminal and other abortions were brought in. The practice then was to place the woman on a table, give an intrauterine douche, and curette the uterus. After curettage the uterus was thoroughly douched with a 1 to 5,000 solution of bichloride of mercury, followed by sterile water. Dr. Bellamy exhibited a double return flow intrauterine douche tube that he had devised and used with much satisfaction.

Dr. Joseph B. Cooke, in discussing Dr. Stone's paper, said that, while the subject had been covered in a most interesting and comprehensive manner, he did not believe that the matter of the prevention of puerperal sepsis in private practice could be reached from this point of attack. The proper management of maternity cases in private practice had been treated in detail at one time or another by nearly every contributor to obstetric literature, and the technique of one individual differed from that of another in minor details only. The modern textbooks of obstetrics, without exception, contained detailed instructions for the proper conduct of cases at the homes of the patients, and every physician who practised medicine to-day was or should be thoroughly familiar with some proper technique. The contagiousness of puerperal fever had been known for sixty years, ever since Semmelweiss had instituted the practice of disinfection of the hands with chlorine water in the maternity wards of the Vienna General Hospital in 1843, and our own Oliver Wendell Holmes had published his classical essay on this subject in 1842; and yet the results in private practice to-day were practically the same as they had been sixty years ago. The very fact of the existence of this marked difference between the results of the general practitioner, as taken from life-insurance reports, which showed that puerperal sepsis was nearly, if not quite, as prevalent as ever, and those of maternity hospitals, in which child-bed fever was practically unknown, brought the whole question down to a point, not of scientific knowledge of means and methods but of the conscientious application of perfectly well-known methods in practice.

In the hospital the surgeon worked in the glare of the lime-light, and his every act was open to comment and criticism; in private practice the physician had only his conscience to consider, and until some greater restraint was placed over him there would be no marked improvement in his results. This restraint could come only through education of the public, not in questions of a technical character, which concerned the profession alone, but in a more general understanding of the importance of maternity cases; of the necessity for careful preparation for their proper management, and of the danger, not only of the sepsis that killed, but also of the milder forms of infection which caused permanent impairment of health. When these matters were thoroughly understood by women in general, and they realized fully that a properly conducted obstetric case required careful preparation and minute attention to a great number of details, an improvement in results would show itself at once. The careless, unscrupulous, and criminally negligent practitioner would slowly but surely be forced out of the profession; the man who was "too busy" to examine the urine of his

pregnant patients and otherwise attend to the details of his cases would be accorded the same treatment as was meted out to the captain who was so busy selling tickets (and incidentally making money) that he overloaded his boat and precipitated a disaster by reason of his cupidity; and the famous "little black bag" would disappear from the face of the earth.

The problem of educating the public along these lines was not an easy one, owing to the inherent nature of the subject, but much could be done through the great body of trained nurses by impressing them during their training with the importance of the matter, and urging them to disseminate this knowledge as widely as possible in the private practice of their profession. Also, books by authors of standing and repute, written in a popular style and free from sensationalism and technicalities, would be of value, and it was possible that short lecture courses could be arranged to advantage in connection with the various clubs, societies, and other organizations of women throughout the country. It was needless to say that instruction of this kind should consist only of such matters as were accepted without question or cavil by every well-informed physician, and that all reference to questions under discussion or to methods properly subject to variations of opinion or of personal preference, should be entirely omitted.

Papers, such as the most excellent one now under discussion, no matter how comprehensive, how instructive, or how interesting, were in the nature of "carrying coals to Newcastle," for, the physicians who must be reached were the renegades of the profession, who attended no society meetings, read no medical journals, cared only for the number of patients on their books and the fees that they could demand, and feared nothing but loss of practice and the search-light of public opinion. These men were deserving of no consideration whatever, and the sooner they were held up to scorn the better for womankind and for the profession under whose flag they marched, with whose protecting cloak they were wont to shield themselves when danger threatened, and whose best traditions and practice they were constantly bringing to shame.

Dr. Eben V. Delphey said that the cause of septic infection of the puerperal woman depended upon a number of factors. The first was shock, which predisposed the patient to septic infection by so lowering the vitality of the tissues that they were unable to resist bacterial invasion or destroy the germs after they had passed the outer line of defence. Shock depended very largely upon the personal equation of the patient. There were some patients who were very susceptible to shock and were, therefore, very liable to infection, while other patients, subjected to an equally trying ordeal, escaped. A severe and prolonged labor produced shock, whether the delivery were natural or operative (instrumental or manual). When it was evident that the patient would not be able to deliver herself, it was the duty of the obstetrician to institute operative interference as soon as possible, provided, of course, that the parts were in proper condition for such procedure. The second cause of puerperal septic infection was immediate perineorrhapy. It must be remembered that a torn perineum was not a clean-cut, incised wound but a bruised and lacerated one. When these surfaces were brought together there was bound to be some death of tissue, and this formed the very best culture medium, and at the proper temperature for rapid propagation. Sutures produced coaptation only, and when the laceration was of the first or second degree, the same result could frequently be accomplished by binding the patient's hips and thighs tightly together. By this latter method, if the parts did not unite, there was nothing to prevent free drainage of the wound, as there was when sutures were employed. Moreover, when the patient did become septic, after an immediate perineorrhaphy, usually the first thing to do was to open up the perineal wound, and when we found a pocket of pus we were sure of the cause of the general septic infection. As a result of this free drainage, the temperature commonly dropped in from twenty-four to forty-eight hours. He had done immediate perineorrhaphy in a number of cases, and while his results had been fair they had not been perfect; on the other hand, in secondary perineorrhaphies there had as yet never been other than complete union by first intention. Therefore he had come to the following conclusions: If the laceration was into the rectum some operative endeavor should be made toward its immediate repair; if it was only down to the sphincter it should be a matter of judgment with the obstetrician what was best to do; if the laceration was only through the mucous membrane it should be left decidedly and entirely alone.

He had had three cases of puerperal septicæmia, during the last twelve years, in the five hundred deliveries in which he had himself been the obstetrician. The first case was one in which the last speaker had been associated with him. The woman was a II-para with an anteroposteriorly flattened pelvis, non-engagement of the head at the brim, and prolapsed cord, with a history of a previous extremely difficult labor. After ineffectual attempts with the forceps she was delivered by bimanual version. She suffered severely from shock, and, about two hours later, from postpartum hemorrhage. At the end of the second day the temperature rose, and the diagnosis of puerperal septicæmia was very clear. The second case was one in which the infection did not show itself until the eleventh day of the puerperium, when the infant also had ophthalmia neonatorum due to the gonococcus. The third case was one in which the family would not permit him to use forceps until the patient was in such a state that he refused to continue in attendance unless it was done. The delivery was extremely difficult, and the combined shock was such that she contracted septicæmia, but she, as well as the others, made a good recovery.

One of the best drugs, for the prevention and treatment of puerperal septicæmia, was the old-fashioned infusion of digitalis, because it slowed and strengthened the heart-action and at the same time contracted the muscular fibers of the uterus. As the septic uterus was usually a flabby uterus, allowing septic material to pass through into the general circulation, this contraction prevented such passage. and the drug was therefore doubly effective.

His antiseptic precautions consisted in carefully washing the patient's external genitals with soap and water, and thoroughly scrubbing his hands and forearms with a *new* stiff brush, which he never took away from the patient's home after using. He believed the best antisepsis consisted in using soap and hot water and—first, scrub; second, scrub; and third, *scrub*. After the hands had been thoroughly scrubbed in running water there were not enough germs left on them to do any harm, provided all the other precautions as to the patient had been observed. The lochial discharge was known to be an excellent germicide, and if the patient had not suffered too much from shock, or had not been grossly infected, she was not liable to suffer from septicæmia if the lochia were kept free, because the "bugs" could not swim against the stream.

Dr. A. Ernest Gallant said that he favored immediate perineorrhaphy in all cases except those in which the laceration extended into the rectum. In the latter he preferred to repair the perineum by a secondary operation. If every one would approach a case of labor as the surgeon did an operation there would be very little difficulty in the practice of obstetrics. The proximity of the anus practically made the whole vulva an infected region, and hence it was essential to clip the hair and make free use of the scrubbing brush and soap. He believed, with Williams, that curettage was very seldom necessary, and he was inclined to think that better results would follow from the use of any suitable means for securing good drainage from the uterus. He had devised

a simple instrument for keeping open the cervix for this purpose.

Dr. David P. Austin said that he was accustomed to confine a woman on a cot or bed away from the bed upon which she was to remain after delivery. This seemed to him an important factor in preventing puerperal sepsis. With regard to immediate perincorrhaphy, he said that he regarded this operation as an effective measure for the prevention of sepsis. He favored the use of a curved needle and the deep introduction of the sutures, and deplored the present tendency to employ catgut rather than silver wire.

Dr. Stone said that while he personally preferred to deliver a woman on the back the side position was of value because the field of operation was farther away from the dirty sheets.

Dr. Voorhees said that the point was well taken with regard to the value of the hand in connection with the use of one blade of the forceps as a vectis for securing rotation of the head.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending March 28, 1903:

	Cases.	Deaths.
Measles	314	12
Diphtheria and croup	441	61
Scarlet fever	282	13
Smallpox	1	..
Varicella	131	..
Tuberculosis	345	169
Typhoid fever	46	12
Cerebrospinal meningitis	..	..

Chief Causes of Death: U. S., 1900.—According to the vital statistics of the census of 1900, diseases of the respiratory system still stand among the chief causes of death; the death rate in the United States being 279.5 in every 100,000 population. The death rate in England and Wales is 324.1 per 100,000 population. In the cities of the United States the death rate for this class of diseases is 335.1; in the rural portion, 199. By States, the highest rate is in New York, 323.5; the lowest in Michigan, 172.7. By nationality, the rate for those born of Italian mothers is highest, 705.5 per 100,000; second, of Irish mothers, 365.3. Mothers, German, 245.7; English or Welsh, 228.7; Scotch, 221.1; United States, 211.6; Scandinavian, 209.8; Canadian, 209.4; French, 208.6, the lowest rate.

By age: deaths in the first year, children of Italian mothers, 7,049.4, in 100,000; population of French, 3,872.4; United States, 2,225.6; Polish, 2,219; Bohemian, 2,202.2, lowest. By sections: Middle Atlantic, 188.4, in 1,000 deaths; Southern Mississippi River belt, 178.1; South Central Appalachian belt, 169.5, for the three highest rates; South Atlantic coast, 122.2; Pacific coast, 117.6; Gulf coast, 115.9; for the three lowest rates. By months, March and April, highest death rate; July and August, lowest. Diseases of the circulatory system, United States, death rate for the census year, 150.1; for 1890, 134.2. The three highest by nationality of mother were: of Irish mothers, 205.5 per 100,000; of French, 176.7; Scotch, 171.8; three lowest: born of Scandinavian mothers, 68.8; of Hungarian and Bohemian, 66.4; of Russian and Polish, 55.4. Of English and Welsh mothers, 165.7; of German, 144.9; of United States, 126.5 (largely of children under 5 years); of Canadian, 90.4; of Italian, 76.4.

Fifty thousand seven hundred and sixty-six persons died in the United States during the census year of apoplexy and paralysis. The highest rate was in the rural districts, 127.5, in 100,000 population; the rate in cities was 98. The rate by sex was, for males, 111.6; females, 108.6. These rates are an increase upon those of 1890, and the highest rate by age is from 65 years upward. By nationality at 65 up the highest rate was for those born of Russian mothers, 1,402.7, in 100,000; of English and Welsh mothers, 1,215.6; of French, 1,211. For all ages, highest, of Irish mothers, 133.2. Next of French, 132.7; of Scotch, 131.9; English and Welsh, 127.6; of German, 95.3; of United States, 95. Lowest, of Russian and Polish, 21.7; of Italian, 27.9; Scandinavian, 34.4; Canadian, 48.6.

Diseases of the nervous system—death rate: persons born of Irish mothers, 227.1; of French, 221.7; of English and Welsh, 221.3; of United States, 207.6; of German, 178.8; of Hungarian and Bohemian, 141.2; of Scandinavian, 114.5; of Russian and Polish, 114.3, per 100,000 population.

Diarrhœal diseases—death rate: cities, 156.6; rural districts, 97.2; death rate for colored, 205.8; white, 129.5. There is a great decrease in the rate in all sections and all classes since 1890.

Typhoid fever—death rate: from Scandinavian mothers, 41.9; other foreign, 37.9. Three lowest from Russian and Polish mothers, 17.3; Scotch, 19.8; Italian, 20.9. By sections, highest rate south of Mason and Dixon's line, westward to western Texas and Kansas.

Death rate from cancer: from French mothers, 97.8; Scotch, 89.7; German, 84.4; Irish, 83.9; English and Welsh, 78.3; United States, 53; Hungarian and Bohemian, 34; Russian and Polish, 28.6; Italian, 24.7. By States: Vermont, 90.2; Maine, 88.5; lowest, New Jersey, 56.4; Michigan, 63.2.

If we single out consumption from other diseases of the respiratory systems, the death rate by sections is, for the Pacific coast, 153; Central plain, 138; South central, Appalachian region, 132.4; Central Appalachian, 81.4; North West, 86.5; South West central, 92.6, in 100,000 population. A general decrease in the past ten years: ratio, 122.3 to 109.9.

Health Report.—The following cases of smallpox have been reported to the Surgeon-General, U. S. Marine Hospital Service, during the week ending March 28, 1903:

SMALLPOX—UNITED STATES.

			CASES.	DEATHS.

THE TECHNIC OF NEPHROPEXY, WITH SPECIAL REFERENCE TO A METHOD OF ATTACHING THE KIDNEY AS NEARLY AS POSSIBLE IN ITS NORMAL POSITION.*

By RAMÓN GUITÉRAS, M.D.,
NEW YORK.

THE best method of treating a movable kidney is a subject which has interested surgeons since the time of Franciscus de Pedemontium, who, in his work, "De Dislocatione Renum et Vesicæ," written in the beginning of the Fourteenth Century, was the first to describe this condition.

For many years the only treatment of movable kidney consisted of palliative measures, such as rest and the application of a variety of belts, supports, and trusses, some of which are still in the market and are used with varying success.

In 1874 Greenville Dowell of Galveston, Tex.[1] passed a large curved needle with a seton through the abdominal wall and through the kidney, and allowed it to remain *in situ* for three months, so as to promote adhesions and prevent the mobility of the tumor. The kidney was subsequently removed, but some authors claim this to have been the first nephropexy ever performed.

In April, 1881, E. Hahn of Berlin performed the first operation for the attachment of a movable kidney.[2]

The description of his operation, for which Le Dentu later suggested the name of *nephropexy*, was as follows: The patient was anæsthetized, placed in the lateral position, and the kidney was exposed by a vertical incision from the twelfth rib along the outer edge of the erector spinæ to the iliac crest. The kidney was then brought out into the wound and sewed to the edges of the incision by means of from six to eight catgut sutures which passed only through the fatty capsule. The wound was then packed with carbolized gauze and allowed to heal by granulation.

In the state of surgery prevailing in 1881, Hahn's operation was considered extremely hazardous by a number of authorities. It was said that the fixation of a movable kidney was an impossible task; one that was apt to cause permanent injury to the kidney; possibly uncontrollable hemorrhage, if the parenchyma had been pierced; and one that would in the end terminate with redetachment of the organ. In spite of this opposition, Hahn and a number of other surgeons in Germany, Italy, and America continued to practise nephropexy, and to observe the results obtained therewith. It is only within the past ten or twelve years, however, that enough material has accumulated to show that excellent results as regards fixation and relief from symptoms may be obtained by the operation first attempted by Hahn.

Almost every surgeon has attacked the mechanical and surgical problems presented by nephropexy in a different manner. The variations presented depend upon the operator's conception of the object to be attained, and of the best mode of attaining it in kidney fixation. In this way the ingenuity expended upon modifications of the technics of nephropexy since Hahn has been astonishing and the array of methods bewildering.

It seems to me that the best method of discussing the technics of the various operations introduced within the past fifteen years is to classify them under headings corresponding to the main features characterizing each operation.

Nephropexies vary in their technic in the following cardinal points: (1) As to the mode of approach to the kidney, *i. e.* as to the incision; (2) as to the part of the kidney utilized in the fixation; (3) as to the material used in the fixation; (4) as to the portion of the parietes to which the kidney is attached.

1. The Incision.—The two chief varieties of incisions used are the abdominal and the lumbar.

The *abdominal incision* is still used by a few surgeons. It was first employed by Rosenberger,[3] who made an opening in the peritoneum and attached the kidney half intraperitoneally and half extraperitoneally after passing one half of it through the peritoneal slit. This operation has not found any followers.

Abdominal incisions have also been used by Kendall Franks[4] and by R. H. Reed.[5] Neither of these operations have gained popularity, as the advantages of the lumbar method are now generally recognized. Reed's operation involves the passage of sutures through the whole kidney and the entire thickness of the lumbar wall from the abdominal side.

A combined lumbar and abdominal incision was used by MacArthur,[6] who makes a pocket for the kidney under the lumbar fascia and inserts the organ into this pouch, drawing the edges of the latter with a few stitches. F. C. Ferguson[7] uses both a lumbar and an abdominal incision, and sutures a fold of peritoneum pushed from in front into the lumbar cut, thus securing a pocket supporting the kidney.

The *lumbar incision* is preferred by nearly all modern surgeons. There are three main types of incision employed in lumbar nephropexy: (1) The vertical; (2) the vertical, combined with an oblique prolongation; (3) the oblique, following the edge of the ribs.

The vertical incision begins below the twelfth rib, at the point of junction of this rib with the outer border of the erector spinæ muscle, and runs along this border down toward the crest of the ilium. When more room is needed on account of the narrowness of the iliocostal space, the incision may be prolonged by curving it outward and downward in the direction of the anterior superior spine of the ilium. These incisions are the types generally used at present. Some surgeons, however, prefer to cut obliquely along the lower border of the

*Read before the Rhode Island State Medical Society, Providence, R. I., at its quarterly meeting, December, 1902.

twelfth rib, *i. e.* Küster,[8] Lobstein,[9] and Championniere,[10] and several other operators. In each instance this incision is favored by these authorities because it adapts itself to the further steps of the operations employed by them.

11. The Part of the Kidney Used in the Fixation.—In this respect nephropexies present the greatest possible varieties of types, each operator often not only having his own modification, but from time to time, as experience teaches him, modifying his own technic. It would be useless to describe separately in detail all the methods of preparing the kidney for fixation which have been employed since Hahn's first operation, and I shall, therefore, confine myself to a brief consideration of the "type-forms," *i. e.* the more striking variations.

The parts of the kidney used for fixation by different operators have been as follows: (1) The fatty capsule; (2) the fibrous capsule; (3) the parenchyma; (4) a combination of two or more of the preceding with or without decapsulating the kidney.

In the early operations, Hahn fixed the kidney by means of the *fatty capsule alone*, but it was found that this method gave only temporary relief, and that kidneys thus treated became detached in a short time. Hahn himself set about to improve his own technic from the start. His first modification was to split the adipose capsule and to separate a part of it from the posterior surface of the kidney, and then to introduce and suture this portion into the wound. He also suggested that the sutures be continued further down below the kidney, giving the organ a better support below than his original operation. The original operation of Hahn, suturing the capsule to the lumbar wall, was soon abandoned, even by Hahn himself, and to-day it has been universally rejected for more secure methods of fixation.

The first operation, in which the sutures included *the fibrous capsule in addition to the fatty capsule*, was performed by Hahn at the suggestion of Bassini[11] in 1882, while the first operation in which the needle was passed through a portion of *renal parenchyma* is credited to Delhaes.[12] Newman[13] of Glasgow employed a similar technic, but passed his sutures through the fatty capsule, the fibrous capsule, and the parenchyma, and since then a number of operators have followed his example. Gradually, however, the fatty capsule was relied upon less and less as a means of fixation, and within the last twelve years but few operators have included it in their sutures. Angerer,[14] in 1891, and Bazy still employed this technic. Bazy[15] passed his three catgut sutures through the capsule and superficially through the parenchyma, and attached them to the eleventh intercostal space, massing the adipose capsule under the lower pole of the kidney. This massing of the fatty capsule as a means of support from below has been since then emphasized as useful by Noble.[16]

The *fibrous capsule*, with or without the parenchyma, next came in for the greater part of attention as a point of attachment for the fixation-sutures. But few surgeons pass their sutures through and under the unopened fibrous capsule alone, without first incising or reflecting it, and without going through the parenchyma, Kellog's method being one of the few instances of such a practice. Most operators who pass sutures through the unopened fibrous capsule also pass them through a portion of the parenchyma. The operators who follow this last-mentioned type of technic are too numerous to mention, and for some years have constituted the majority of surgeons who have performed nephropexy. Among the prominent operators who used this method in some form were Duret, Guyon, Albarran, Henry Morris, Treves, Küster, and Keen, each surgeon modifying the exact disposition of the sutures and their depth of penetration to suit his own conception of the mechanism of kidney support. In order to secure better adhesions, some surgeons who follow this method scarify or cauterize the fibrous capsule in the area that comes into contact with the lumbar wall. Bruce Clarke[17] scrapes the surface of the kidney before drawing the sutures, while Zatti[18] cauterizes the fibrous capsule with the solid stick of silver nitrate.

The realization of the fact that sutures alone cannot be relied upon for the permanent fixation of the kidney in the lumbar fossa was evolved from the gradually accumulating experience of various operators, and within recent years a number of methods of nephropexy have been introduced in which, in addition to sutures, *adhesions were formed artificially between the kidney parenchyma and the muscles of the lumbar wall.* This was accomplished by the introduction of a maneuver known as decortication or stripping of the fibrous capsule from a portion of the kidney, especially from that portion which comes into contact with the parietes.

Jordan Lloyd,[19] an English surgeon, was the first to practise the procedure of decortication in nephropexy. He "purposely stripped off a portion of the capsule over an area one inch in diameter, and then secured the kidney to the lumbar tissues" by two catgut sutures introduced through the fibrous capsule and parenchyma close to the edge of incision.

Gradually, the denudation of larger areas was attempted, at first in animals by Tuffier,[20] who found that the harm resulting to the kidney from such a procedure was not appreciable, while the adhesions which form between the denuded parenchyma and the lumbar wall were firmer, more vascular, and more permanent than those which form between the fibrous capsules of undenuded kidneys and the loin tissues. Tuffier's experiments showed that the fibrous capsule interferes with the formation of adhesions, and that when it was removed the kidney grew so firmly glued to the parietes that it ruptured before the adhesions were torn. While decortication since then has been adopted as an essential feature of fixation by a large number of surgeons, there are still some authorities[21] of the first rank who consider such procedure useless.

The methods of decortication are numerous, but they may all be divided into two main groups: (1) Those involving the passage of sutures through the capsule and also through a portion of the parenchyma. (2) Those involving the passage of suture through and beneath the capsule alone.

The list of surgeons who, through their writings, show that they fix the kidney by passing sutures through the fibrous capsule and the parenchyma after decorticating a variable portion of the organ includes the names of Lloyd[22], Tuffier,[23] Rose,[24] quoted by Wolff; Hahn,[25] quoted by Frank; Jonnesco,[26] Courvoisier,[27] Terrillon,[28] Tricomi,[29] Schiassi,[30] and Von Torõk [31]

The principal modifications of the fixation methods that involve passing sutures through and beneath the fibrous capsule alone after decorticating a portion thereof, are those of Newman,[32] quoted by Morris,[33] Jacobson,[34] quoted by H. Morris; Lane,[35] Law,[36] quoted by Morris;[21] Edebohls,[37] Selmi,[38] A. B. Johnson,[39] quoted by Edebohls; Baldwin,[40] Montgomery,[41] and R. T. Morris.[42]

The variety of operations which come under this particular heading is very great, simply because there is an almost infinite variation possible in the size, shape, and position of the fibrocapsular flaps

and in the method of introducing sutures into the reflected portion; the unreflected portion, or into the edge of reflection of the capsula propria. Some surgeons, *i. e.* Rose, denude the entire kidney, while others, *i. e.* Newman, decorticate a strip along the outer border of the organ not wider than a third of an inch. A variety of geometric figures has been employed in planning the areas denuded. An example is the operation of Arbuthnot Lane,[35] who makes radiating incisions and raises ten triangles on the posterior surface of the kidney and sutures them in a complex manner to the lumbar incision. A number of surgeons, *i. e.* Jacobson, Edebohls, etc., usually strip one-half of the anterior and posterior surfaces, reflecting their flaps from a longitudinal incision along the outer edge of the kidney.

The position of the sutures and their direction have undergone so many variations that it is impossible to give even the chief ones.

III—The Material Used in the Fixation.—(*a*) Sutures: (1) Catgut: (2) chromicized catgut; (3) kangaroo tendon; (4) silk; (5) silver wire.

(*b*) Other material: (1) Muscle tendon (quadratus lumborum (Sottocasa); erector spinæ (Veuillet); (2) gauze strips and packing (Senn, Deaver, Myles, Riedel); (3) periosteum of a rib (Derocque); (4) drainage tubes (Fischer, Beyea).

This list shows at a glance that almost every conceivable material has been employed in the fixation of the kidney. Chromicized catgut, lasting forty days, is now used by most surgeons in these operations, especially by those who decorticate and do not pass sutures through the renal substance. Silver wire is used by Küster[43] and by a few other surgeons. Catterina[44] probably outclasses all other operators for the oddity of his method of nephropexy. He "found it convenient and effective to imprison the kidney in a net or cage of silver wire, which he suspended from the twelfth rib," and claimed that no injury results to the kidney or the surrounding tissues from this procedure. Witzel[45] fastens the kidney by means of silver wire sutures to a net of the same material placed in the superficial fascia of the loin.

Operations without the use of sutures have been advised by a considerable number of surgeons, but are not looked upon with favor by most men doing renal surgery. Deaver[46] of Philadelphia exposes the kidney, deprives it of its fatty capsule, scarifies the fibrous capsule, and passes two bands of gauze in front of the poles of the organ; replaces the kidney and packs the wound with gauze, tying the ends of the bands over the packing. He renews the dressing in eight days, and healing usually takes place by granulation in five weeks. Deaver's operation was a modification of the method published by Senn[47] in 1897. A combination of the suture operation and the method that employs gauze tampons is that of Riedel[48], which does not find many followers on account of its complexity and the long convalescence following it. A similar combined operation is that of Jaboulay[49], and Myles[50] uses simple denudation and tamponade.

Muscle tendons have been employed in fixation by two operators, Veuillet,[51] suggested the use of a thin strip of the erector spinæ, and Sottocasa[52] a portion of the quadratus lumborum for this purpose, sewing this bundle into a furrow made in the convex border of the kidney by cutting through the fibrous capsule.

The periosteum of the twelfth rib has been made the means of suture by Derocque[53] after having resected the rib, but this procedure involves the danger of injuring the pleural sac or the lung.

Finally, bone drainage tubes have been inserted and sewn into place in such a way by Fisher[54] as to support the kidney, and rubber tubes were looped around the poles of the kidney by Beyea[54] for the same purpose.

IV—The Part of the Parietes Used in the Fixation.—In this respect nephropexies vary as follows: The sutures may be fixed to: (1) the lumbar wall in its entire thickness; (2) the lumbar muscles without the skin and superficial fascia; (3) the twelfth rib; (4) the eleventh intercostal space.

The early operators, and many of the later ones, passed their sutures through the entire thickness of the lumbar wound. Of late years a number of surgeons began to bury their sutures under the skin and fasciæ, tying them over the muscles of the lumbar wall.

The twelfth rib and the eleventh intercostal space have also been made the point of attachment of renal suspension sutures, for the first time by Ceccherelli[55] and later by De Paoli.[56] Ceccherelli passed four catgut sutures through the upper poles of the kidney and looped them over the twelfth rib. De Paoli cut through the last rib, thus gaining space upward, and attached the kidney by means of a number of sutures passing through the adipose capsule to the last intercostal space.

The Author's Technic.—The technic used by the author at present was spoken of by him for the first time before the Alumni Association of the City Hospital, November, 1901, in the course of a discussion on movable kidney; again at the April meeting of the same association. It was demonstrated at the October, 1902, meeting of the Harvard Medical Society of New York and at the November, 1902, meeting of the American Urological Association, on which occasions the subject was presented with illustrative cases.

In working out the technic which I am about to describe, I have been guided by the following principles, which experience and the study of the literature of the subject have taught me to regard as the rational basis of an efficient and safe nephropexy.

Principles of Nephropexy.—(1) The kidney should be fixed in as nearly its normal position as possible. (2) It should be fixed in such a manner that it subsequently does not (*a*) sink in the vertical plane, (*b*) rotate on the vertical axis. (3) The kidney may, however, be allowed to turn to a certain extent on its horizontal axis, such a rotation being normal with each respiratory act, according to Küster.[57] (4) The permanence of the fixation should not be made dependent on sutures, no matter what suture material be employed, but upon firm adhesions between the kidney parenchyma and the lumbar wall. (5) The material used for suture should be one that holds long enough to allow adhesions to form and yet is ultimately absorbed without injury to the parts. (Chromicized gut is the only material that corresponds to these requirements.) (6) The operation should be as simple as possible; should include as few stitches as possible, and should take the least possible amount of time.

Comparatively little progress has been made, with all the modifications of nephropexy, in securing the kidney in its normal position. Some operators who have contributed to the literature of the subject declare frankly that they anchor the kidney in preference in a position that appears convenient to them, believing that the functional result is just as good in the end as when the kidney is fixed in its original place. These operators fix the kidney in the iliocostal space, midway between the last rib and the iliac crest. They make no attempt to secure the organ in its normal position, with the twelfth rib

and the eleventh intercostal space overlapping its upper third.

The advantages accruing from the fixation of the kidney in its normal position are, in my opinion, so great that it is worth while taking pains to

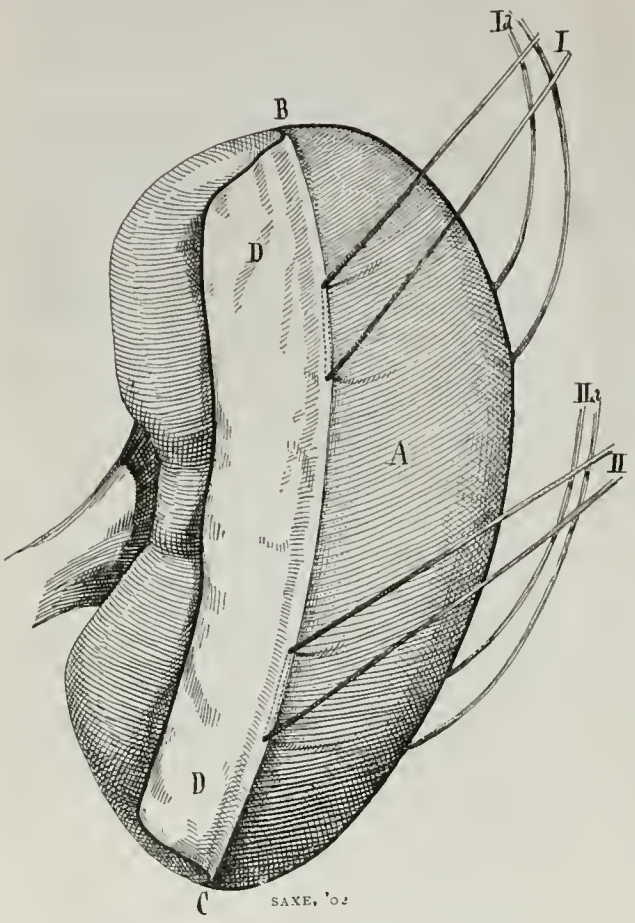

Fig. I.—Shows the posterior aspect of the right kidney, the outer half of whose posterior surface (A) has been denuded of its capsule up to a line (B C) where the capsule has been reflected inward like the lapel of a coat (D D). The posterior retention sutures I and II are inserted into the reflected edge, as described in the text; running through both layers of the capsule, under and parallel to this edge along the dotted lines. The anterior retention sutures Ia and IIa appear in the next plate.

secure this object as nearly as possible in planning the technic of the operation.

In many of the modern methods two errors are, to my mind, made as regards the normal position of the kidney: (1) That they fix the organ below the renal fossa. (2) That they attach it to the parietes with its convex border pointing almost backward instead of outward and slightly backward, as this border normally points. Both these errors I have endeavored to avoid in the operation which I have been performing of late and which I am about to describe below.

A consideration of the normal position of the kidney will at once bring out the differences between this position and that assumed by the kidney after fixation by the methods in vogue with many surgeons at present.

The kidneys are situated in the loins between the transversalis fascia and the peritoneum, and are separated from the spine by the psoas. Their poles correspond in the average case to the level of the lower border of the eleventh dorsal vertebra and of the upper border of the third lumbar respectively, the right kidney being often, though not always, slightly lower than the left. The upper poles approach each other slightly more than the lower. The horizontal axes of the kidneys form an angle with the sagittal plane of about 60°, opening backward, the apex of this angle being in front of the center of the first lumbar vertebra. Certain variations, though not extensive ones, occur normally in this angle.

The extent to which the eleventh and twelfth ribs cover the upper part of the kidneys varies with the obliquity of the ribs and the angle of approachment of the upper poles. According to Luschka,[58] two-thirds of the kidney are covered by the eleventh and twelfth ribs, while Pausch, quoted by Küster,[59] says that the kidney is divided into two equal parts by the twelfth rib.

A kidney which is fixed in the manner adopted by the operators referred to is, therefore, very far from being in its normal position.

The principal feature of the technic employed by me is the decortication of one-quarter of the circumference of the kidney, the quarter selected being that nearest to the convex border on its posterior surface. The kidney is so sutured then to the parietes, that it not only remains quite near its normal level, but also is attached at a normal angle in its vertical axis, *i. e.* with the convex border pointing outward and slightly backward.

Description of the Technic.—The ordinary posterior vertical incision already described is made. The kidney is freed from its fatty capsule, the redundant part of which is trimmed away especially at the posterior surface of the kidney, and the organ is brought out of the lumbar wound. An incision is now made through the fibrous capsule, from the upper to the lower pole, over the convexity of the kidney. The fibrous capsule is separated from the parenchyma on the posterior surface of the kidney beginning at the convex border until one-

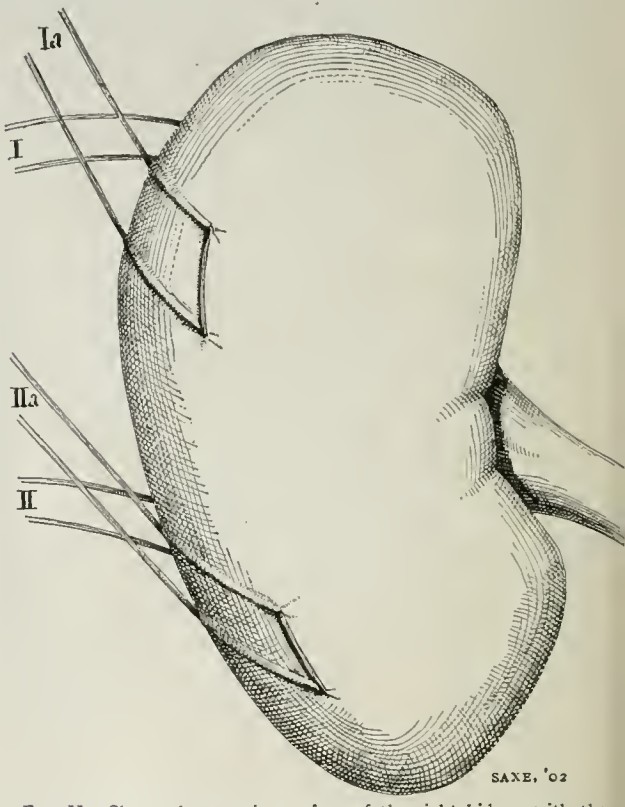

Fig. II.—Shows the anterior surface of the right kidney, with the anterior retention sutures Ia and IIa passing underneath and over the capsule at a distance of three-fourths of an inch from the cut edge, thus obtaining a firm hold on the fibrous coat. I and II are the posterior anchoring sutures shown in Plate I.

half of that surface is bare. The anterior surface is left covered with fibrous capsule. The posterior abdominal wall for about an inch on either side of the wound is now rubbed with "adhesion-promoters," gauze, or brush to allow the denuded portion to come into contact with a part of the wall that will easily adhere.

Two retention sutures of chromicized catgut are now passed through the peeled-back capsule at the point of reflection, the upper suture at the junction of the upper and middle thirds of the kidney; the lower at the junction of the lower and middle thirds of the organ. In passing these posterior

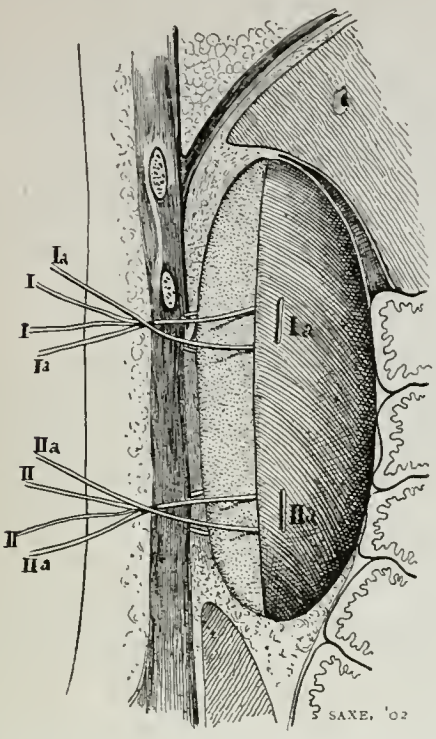

FIG. III.—Shows a vertical section of the body at a point just outside the convexity of the kidney with the anchoring sutures lying loose. It is easy to see how the posterior surface will be pulled into place when the sutures are drawn up. I and II are the posterior, Ia and IIa the anterior sutures.

sutures the needle is inserted near the edge of reflection, including *both layers* of the capsule at that point, passing under the layer still adherent to the parenchyma, *i. e.* between the kidney substance

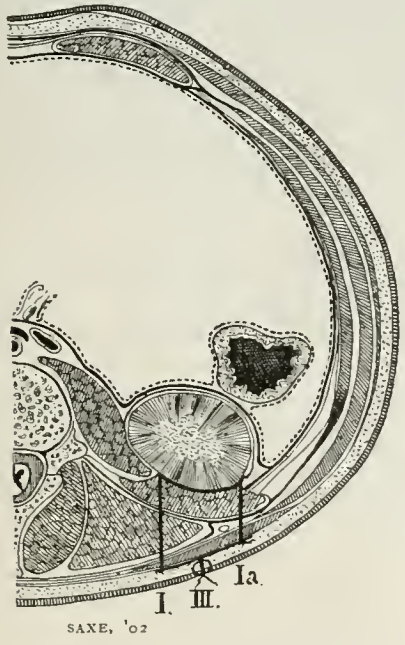

FIG. IV.—Transverse section. Kidney held in place by anchoring sutures tied under skin. I and Ia anchoring sutures, and III skin suture.

and the capsule, for three-quarters of an inch, and emerges through the outer reflected layer, carrying its strand of chromicized catgut (Fig. I). In this way both layers contribute to the support of the sutures, securing them doubly against tearing out. The ends of these sutures are held apart in pairs by means of clamps outside the wound.

The two anterior retention sutures are next inserted at levels corresponding to those of the posterior set, as shown in Fig. II. The suture is threaded to a blunt needle, which is passed under the edge of the cut capsule to a point situated three-quarters of an inch from this edge on the

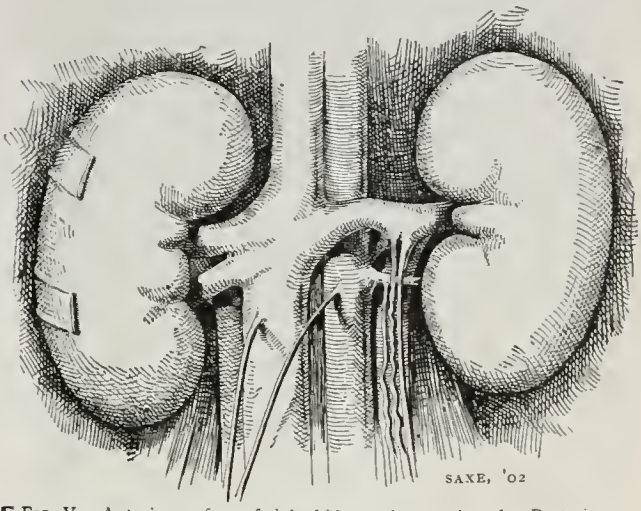

FIG. V.—Anterior surface of right kidney when anchored. Posterior layer of parietal peritoneum and other viscera have been removed.

the anterior surface. There it pieces the capsule, and then passes *over* the capsule for the space of three-quarters of an inch, vertically; then again pierces the capsule from without inward, and running *under* it emerges at the free edge of the fibrous coat, at the convexity of the organ.

The upper posterior and anterior sutures are then passed through the muscles and fasciæ of the loin, the former three-quarters of an inch to the inner side of the incision, just below the twelfth rib, and the anterior in a corresponding position on the outer side. The lower sutures are now passed through the muscles and fasciæ in the same manner

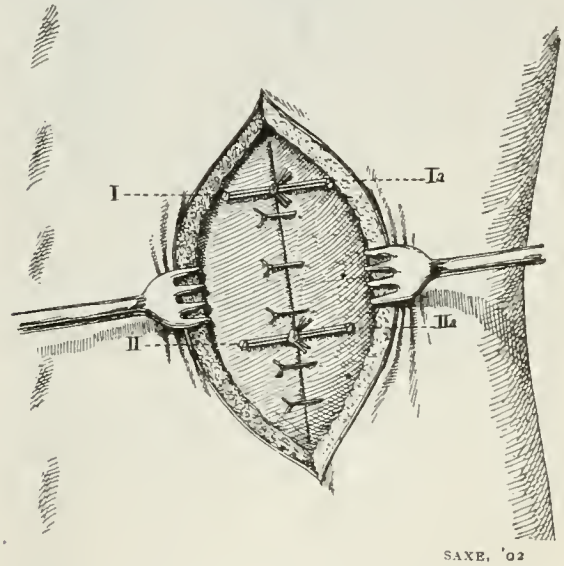

FIG. VI.—Shows the gaping skin incision in the right loin, with the superficial fascia and muscular planes beneath united by fine interrupted sutures. I and II are the knotted ends of the posterior anchoring sutures, which have been drawn and tied tightly over the muscles. Ia and IIa are the knotted ends of the anterior sutures which have not been drawn so tightly as the posterior ones. The ends of the upper set and those of the lower set of sutures are tied together over the muscular wound.

as the upper, occupying positions corresponding to those in which they were placed in the kidney capsule. The muscular edges of the abdominal wall are then brought together by means of the requisite number of interrupted sutures, to insure good approximation. The upper and lower posterior retention sutures

are next tied over the muscular wall, thus bringing the middle vertical part of the back of the kidney firmly against the parietes. The upper and lower anterior sutures, are tied over the muscles with just enough traction to support the kidney at the outer part of the decapsulated area. The loose ends of the upper anterior and upper posterior sutures are now tied together over the muscular incision (Fig. VI), and the ends of the lower sutures are tied in the same way. Finally, the skin layer of the incision is closed with three or more interrupted sutures, and the usual dressing is applied (Fig. VII).

The chief point in the last stages of the operation is to keep the kidney snugly against the lumbar wall, as shown in Fig. IV, by means of the upper and lower posterior sutures, which must be knotted over the muscles more tightly than the anterior ones. In Fig. III we see a vertical section through the body, just outside of the convex border of the kidney. In this sketch the sutures are slack, because they have not yet been tied. It will be readily seen that when they are pulled taut the kidney will be very nearly brought into its normal position against the muscles, with its convex border pointing out-

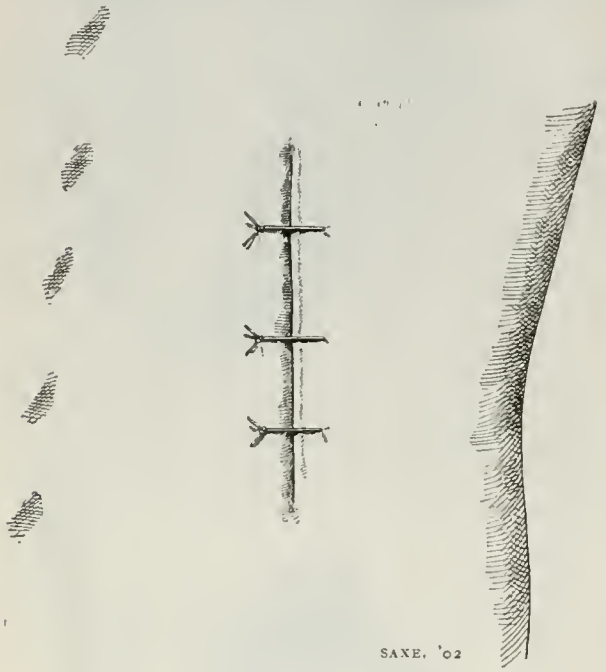

FIG. VII.—Skin incision brought together by sutures.

ward and slightly backward. Fig. V shows the anterior aspect of the same kidney with the anterior sutures running under and over the capsule as described above.

Summary.—I have outlined in detail the various types of operation employed since Hahn in the fixation of the kidney, classifying them according to certain leading features, and have endeavored to show how a kidney can be fixed in as nearly its normal position as possible.

I denude but one-half of the posterior surface of the kidney, that nearest the convexity, leaving the anterior surface intact. I pass my sutures in such a manner through and under the reflected capsule that they hold the organ securely during the formation of adhesions that goes on after the operation, and I tie my sutures over the muscles and fasciæ in such a way as to bring the kidney into close apposition with the parietes, as nearly as possible at the normal level, and in its normal horizontal angle, with the convex border pointing outward and slightly backward.

INTRANASAL OBSTRUCTION AND ITS TREATMENT.

By H. HOYLE BUTTS, M.D.,
NEW YORK.

SURGEON TO THE MANHATTAN EYE AND EAR HOSPITAL (THROAT DEPARTMENT); FELLOW OF THE NEW YORK ACADEMY OF MEDICINE, ETC.

This subject is one of great interest to the general practitioner of medicine and the specialist who has to do with the treatment of the diseases of the throat, nose, and ear.

The nose until recent years has been regarded as a comparatively insignificant organ and one that had little connection with the vital functions of the human mechanism. In times gone by if one had a deformed nose it was considered regrettable from a purely æsthetic point of view by both the possessor and his medical adviser, and little thought was given to the possible injury it might cause to the general health of the owner. Happily, to-day, the necessity of nasal breathing is recognized as being of the very first importance in childhood and early youth, not only in promoting the general health, but in developing and preserving the special senses of hearing, smelling, and tasting.

Nasal obstruction implies mouth-breathing, and it is to the latter evil that one can trace many of the ills of childhood, and much of the unhappiness of adult life, as witnessed in a subject with a poorly-developed physique, who has numerous petty ailments, and whose special senses have been dulled or lost. Mouth-breathing, in the opinion of the speaker, does more to retard the proper physical development of the children of this country than any one other assignable cause.

It seems to be of little use to surround an infant with the luxuries of the times, such as well-ventilated apartments, good food, and proper clothing, if the child is to be allowed to continue breathing through the mouth, for it is being denied a most important thing to its welfare, properly inspired air.

The functions of the nose with its mucous membranes are several, and should always be borne in mind when the organ is under consideration. Foremost of these is to provide a space for the passage of a sufficient quantity of air to distend the lungs. As the volume of air passes through the nasal chambers it comes in contact with the wet membranes and is relieved of many impurities, and at the same time it gathers moisture and heat. Within the nose, in the upper third, are found the delicate terminals of the olfactory nerves, so essential to the keen enjoyment of many of the good things of life. The nose also plays an important rôle in tone production by giving additional resonance to the voice.

A function of the nose second only in importance to that of the passage of air, is that of providing a channel for the drainage of its accessory cavities. Any marked interference with the flow of mucus from these air spaces causes serious, and at times fatal, trouble. It should be remembered that the mucous membranes of the nose and accessory sinuses secrete, under normal conditions, about one pint of fluid each twenty-four hours.

The amount of obstruction found in the nasal chambers varies from a slight one that merely prevents a thorough clearing of the nostrils by the act of blowing, to that of a complete stenosis of both nares. The symptoms arising from an obstruction of the nasal chambers depend upon the extent of the pathological changes of the tissues or the amount of deformity of the nasal septum. In mild cases the principle complaint made by the patient, if an adult, is the accumulation of mucus in the nasal chambers and nasopharynx, in order to dislodge which requires the violent blowing of the nose and the special effort known as hawking. This is a disgusting and offensive habit, and often, in itself, causes the sufferer to seek relief. Such a condition, if left alone, may progress until the habit of mouth-breathing has been established, when the quantity of the secretions is increased and their character changed; frontal and occipital headaches become more or less constant; the oropharynx is dry and irritable, producing a cough, and a chronic catarrhal inflammation of the Eustachian tubes and larynx results.

If the accessory sinuses are involved in the general catarrhal inflammation, and their secretions are retained long enough to cause pus formation, extensive cutting operations will be necessary before the patient obtains relief from prolonged misery and suffering.

In infants and children the usual train of symptoms is that of a discharge from the nostrils, mouth-breathing, snoring and restlessness at night; the complexion becomes white and pasty in appearance; the facial bones remain undeveloped from the lack of internal air pressure, and if the child is old enough to attend school, is very likely to be backward in its studies, and thought to be generally dull and stupid.

The causes of nasal obstruction are many, and it will be the purpose of the speaker to enumerate them and to suggest methods of treatment, surgical or otherwise, that have been found most useful to him in correcting the different forms of this most common condition.

Acute and Passive Hyperæmia.—The simplest form of nasal obstruction is that accompanying an acute rhinitis, which is only transitory and yields to the ordinary treatment of a cold in the head. Repeated attacks of acute rhinitis, however, produce an engorgement of the erectile tissues of the turbinated bodies that may last indefinitely. This condition should be treated by palliative methods; rest should be given to the inflamed membranes by applying soothing and protective oily sprays in the form of liquid albolene, until the relaxed tissues have had an opportunity to return to their normal condition. Usually after a few days' treatment this form of obstruction will disappear and not return until the patient is again exposed to cold or some other irritating cause.

Foreign Bodies.—Two simple forms of nasal obstruction, not requiring surgical interference, may be mentioned briefly, one of which is produced by the accumulation of crusts and changed secretions in the nasal chambers of children who have not been taught to blow their noses, and the second is caused by the presence of other foreign matter. In the former condition, spraying the nasal cavities with a mild alkaline solution two or three times a day, and afterward with an oil, will correct the

trouble. Obviously the treatment for the second form of obstruction is the removal of the foreign body, which usually consists of a shoe button, small pebble, dried bean, or a rhinolith. This is most easily accomplished by spraying into the stenosed side a four-per-cent. solution of cocaine hydrochlorate, allowing it five minutes in which to anæsthetize and shrink the mucous membrane, and then, by means of a strong, angular, toothed nasal-forceps, remove the offending article.

Rhinitis Hypertrophica.—After a long period of passive hyperæmia of the nasal mucous membranes, there is produced a true hypertrophy of these and the underlying structures. This condition, known as rhinitis hypertrophica, is most easily determined by the use of a blunt pointed probe, which is pressed firmly against the suspected tissue; if the indentation made by pressure fills up rapidly as soon as the probe is removed, the tissues are not hypertrophied but simply engorged. If the tissue under inspection offers a considerable resistance to the pressure of the probe, and afterward sluggishly resumes its former contour, we undoubtedly have to deal with a true hypertrophy. Should any doubt exist as to the character of the swollen tissues, an application of cocaine will be found of great diagnostic value, as it will not materially reduce in size a true hyperplastic deposit.

The inferior turbinated bodies are more frequently affected by hypertrophic changes than any of the other parts of the nasal chambers, although the anterior ends of the middle turbinates occasionally become enlarged in the same way.

In the mind of the speaker there is nothing in the way of treatment equal to the judicious application of the electrocautery, for the destruction of this new deposit of tissue. Much has been written of late decrying the use of the cautery in the reduction of hyperplastic tissue in the nasal cavities, but after an experience of many years we know of no method so satisfactory. One can limit its action with certainty, do all that is required to be done and with less inflammatory reaction than by the use of any of the caustic acids so much praised by some writers.

The method of preparing for an operation in the nose with the electrocautery, as pursued by the speaker, is as follows: The nasal chambers are sprayed thoroughly with an alkaline solution, to insure a clean surface upon which to make an application of cocaine; the patient is then requested to blow the nose gently, so that all excessive moisture will be removed; this is followed by a scant spray of a ten-per-cent. solution of cocaine hydrochlorate, into the nostril to be operated upon. As soon as this act is completed, the patient's head is tipped forward to prevent the cocaine from flowing into the nasopharynx and, by paralyzing the velum palati, causing uncomfortable gagging and nausea. The next step is to place in contact with the surface to be cauterized a pledget of cotton that has been dipped in a solution of cocaine of the same strength as was used with the spray, and this is allowed to remain *in situ* for five minutes. After the cotton has been removed the operator will find that the anæsthesia is complete, and a much increased space in which to work has been provided by the depletion of the tissues of their blood supply.

The method of local anæsthesia just described is the usual one for all operations in the nose that do not require a general anæsthetic.

In order to secure a bloodless operation, the cautery point should be brought to a bright cherry heat only, and the electrode should be kept in constant motion all of the time that it is in apposition with the tissues. If the electrode is permitted to become stationary, it will bury itself in the eschar and detach the latter when an attempt is made to release it. This not only causes a hemorrhage, but deprives the wound of a thoroughly aseptic covering.

In cautery operations care should be taken not to touch other and opposing surfaces than those intended to be destroyed, and this can be avoided by not turning on the electric current until the tip of the electrode is in the proper position.

In the use of the cautery for the reduction of these deposits of connective tissue as little of the surface of the membrane as possible should be destroyed, and this can best be done by making parallel lineal incisions in an anteroposterior direction through the soft tissues, down to the underlying periosteum of the turbinates. Make the depth of the incision compensate for the narrowness of the wound. If this method is not observed a considerable area of the mucous glands is obliterated, and the result will be an unduly wide cicatrix upon which crusts will form, much to the discomfort of the patient.

Occasionally other points of hypertrophy than those on the inferior turbinates will demand attention in the nose. If these are isolated spots on the nasal septum, or floors of the nasal fossæ, they may be destroyed by lightly touching with the cautery. Under no circumstances should hypertrophy of the middle turbinated bodies be treated with the cautery, as by extension through the ethmoidal cells, fatal inflammation of the brain may ensue. An hypertrophy in this location, if of sufficient importance to require interference with, is best removed by means of the cold-wire snare.

If the routine described is intelligently carried out, the results will be satisfactory to the patient and surgeon, inasmuch as there will be no pain inflicted and no bleeding.

Beyond spraying a one-per-cent. solution of oil of eucalyptus, in liquid albolene, into the nostril that has been operated upon, the speaker does not believe in post-operative dressings in the nose. Many surgeons plug the site of operation with cotton or gauze; this seems to be an unnecessary and pernicious habit, as it prevents drainage from the wound, is uncomfortable for the patient and whenever the packing is removed it is likely to start bleeding.

The patient is cautioned not to blow the nose violently for several days after the operation, to prevent a possible disturbance to the protecting eschar.

The wound caused by the application of the cautery is painless and heals readily in from two to three weeks; the patient should be seen every other day and sprayed with an alkaline solution for the sake of cleanliness, and should be supplied with a hand-atomizer, containing a one-per-cent. solution of eucalyptus in liquid albolene, with instructions to use it at least four times a day.

The eschar produced by the cauterization should not be disturbed until sloughing of the injured tissues has ceased; this process is usually completed in from five to seven days.

Ecchondrosis and Exostosis of the Nasal Septum.—The cutting operation most frequently performed by the nasal surgeon, is the one for the removal of a spur on the septum. A spur in this location may be a cartilaginous outgrowth from the anterior half of the nasal partition, in which case it is known as an ecchondrosis, or it may be an abnormal growth of bone springing from its posterior half, when it is described as an exostosis.

Spurs of the nasal septum are generally due to a chronic catarrhal inflammation of the mucous mem-

branes and their underlying structures, but they may be the result of a reparative process when a fracture of the bone or cartilage has occurred.

To the speaker's way of thinking the most important thing to be considered in connection with the subject of nasal spurs is: When should they be removed?

That anyone who can illuminate the nasal fossæ can also, as a rule, detect irregularities of the septum, explains in a measure the great number of unnecessary operations that have been done in the nose, to the past discredit of rhinology.

For the guidance of those who, through inexperience, are in doubt as to when they should operate, the following rules are laid down:

1. When a septal spur seriously impairs the respiratory function of a nasal fossa, it should be removed.

2. When a septal spur impedes the drainage from an accessory sinus or a nasal fossa, it should be removed.

3. When a septal spur is in contact with opposing structures, it should be removed.

If one limits one's surgical interference to the conditions just described, one will not be open to criticism, and will probably feel the satisfaction of having relieved the symptoms for which the operation was performed.

Septal spurs, whether composed of cartilage or of bone, are best removed by means of the nasal saw. There are many patterns of this instrument in use, such as angular saws, straight ones, those that are detachable from the handles, and saws that cut only on the forward stroke, while others cut both ways.

The speaker, in selecting a nasal saw, gives the preference to one that is made in a single piece and is straight, has a moderately stiff blade and a double row of coarse teeth on the under side, set to cut on both the forward and backward strokes of the instrument.

After cocainizing the site of operation, and assuring oneself that the saw is absolutely aseptic, there are no preparations to make beyond wrapping half a dozen carriers with small pledgets of cotton, to be used in wiping away blood-clots that form during the progress of the work.

In engaging the saw with the spur to be removed, it is advisable to cut from above downward, when practicable, as in this way more power can be exerted and the tissues severed more rapidly. It is important to complete the operation as quickly as possible and without removing the saw, for with the blood flowing freely the patient is likely to become somewhat demoralized and to retard the progress of the operator.

When the growth has been cut through it will be found lying in the bottom of the nasal fossa, and sometimes attached by a shred of membrane, from which it may be freed by the use of a pair of nasal forceps.

After the bleeding has stopped the nose is gently sprayed with eucalyptus and albolene, and a piece of cotton is tucked loosely into the vestibule of the nostril to prevent the dripping of blood while the patient is returning home.

The operation may be made a bloodless one for the time being by the use of a two-per cent. solution of the suprarenal extract, or of a solution of adrenalin chloride, 1-1 000. This method may be of advantage to the inexperienced operator, as it permits him to see the progress of his labor, but the hemorrhage, when it does come, a few hours later, is likely to be much more profuse than as if ischæmia had not been induced.

The preference of the speaker is to deal with the hemorrhage at the time of the operation at his office rather than at the patient's home, perhaps in the middle of the night. There is no doubt but that secondary or delayed hemorrhages are more frequent in nasal surgery since the introduction of suprarenal preparations than ever before. In operations on the nose when these extracts are not used the bleeding occurs at the time, but ceases spontaneously in a short while, and beyond a slight oozing of blood until the patient retires that night, no difficulty is experienced.

If hemorrhage should persist after the operation, it can be controlled by throwing into the nose, with a syringe, a small quantity of hydrogen peroxide, or by tamponing the nostril with strips of gauze.

Deflections of the Cartilaginous Septum.—As causes of intranasal obstruction next in frequency to those already mentioned, the deflections of the cartilaginous septum are conspicuous.

Deflections of the septum are so common that it is the exception to find a nose that is not so deformed. When one considers the number of knocks and bumps that this prominent and yielding portion of the face receives in youth, it is not surprising that a straight and symmetrical one is rarely observed. According to many authorities, another explanation of these deflections is found in subjects who have a high palatine arch, which prevents, by space limitation, the proper expansion of the cartilaginous septum in its superio-inferior directions, thereby forcing it to bend to one side or the other.

There can be no doubt as to the great amount of injury to the general health and special senses that may be wrought by a much-deflected cartilaginous septum, and for this reason the deformity should be corrected as speedily as possible if sufficient room cannot be gained by the reduction of the soft tissues. The symptoms accompanying this condition are the usual ones of nasal obstruction, to which may be added the reflex phenomena of asthma, chorea, and spasmodic stricture of the œsophagus, and also the manifestations of rhinitis vasomotoria periodica (hay fever).

In classifying deflections of the cartilaginous septum for the purposes of operation, we are accustomed to divide them into two general groups. When the septum is curved to one side only and its surface in the obstructed nostril is smooth and rounded, it is regarded as a simple deflection. When the deflection is marked by a sharp angle at its apex, with a large hyperplastic deposit overlying it, or there is a combination of both the rounded and angular deformities, it is termed a complex deflection.

The same three rules as were laid down for the guidance of the operator in dealing with spurs on the nasal septum are applicable here, when the question of surgical interference arises.

The speaker does not believe that because a septum is slightly deflected, or is not symmetrical, that it must be operated upon. When, however, it has been decided that an operation is advisable, the method suggested by Asch, in 1890, will be found highly gratifying in its results. It has been tried in several hundred cases in the Manhattan Eye and Ear Hospital since 1891. These cases included all the varieties of deflections of the cartilaginous septum, and when the technique of the operation has been properly carried out, there have been no failures.

The following is a description of the Asch operation in detail, quoted from an article by the speaker in the Annual Report of the Manhattan Eye and Ear Hospital, 1896:

"The patient, lying on his back, having been

etherized to a point bordering on complete anæsthesia, his head is brought well over the end of the operating table, so as to be slightly dependent. This position of the head is necessary to facilitate the escape of blood from the nose and pharynx by gravitation, and to decrease the liability of its entrance into the larynx and trachea. The ether cone being removed, the head of the patient is held firmly between the hands of the anæsthetizer, and the operator introduces a little finger into the stenosed naris to determine the point of greatest convexity of the cartilaginous septum. If this is found impossible on account of existing adhesions between the septum and the lateral wall of the nasal fossa, a curved gouge is used to sever the obstructing bands of tissue. Having located the point of greatest deflection, the operator carries into the stenosed naris the non-cutting blade of the Asch angular scissors, and the other and wider blade into the opposite nostril. The incision is then made through the septum by approximating the handles of the instrument, and is accompanied by a snapping sound that is characteristic of the completion of the act. On the proper performance of this first incision is dependent, to a great extent, the result of the operation. It should be made parallel with the plane of the floor of the nose and through the point of greatest convexity of the septum. The hemorrhage is decidedly brisk from now on, but, as the patient is by this time only in the primary stage of anæsthesia, with a restoration of the reflexes, no danger of asphyxiation from inspired blood need be feared. The second incision is now made with the straight pair of scissors at right angles to the previous one and intersecting it as nearly as possible at its center. The patient is now turned over on his side and the accumulated clots of blood are allowed to flow from his pharynx and nasal fossæ; a little more ether is given, and after a return of the patient to his former position an Adams' septal forceps is introduced, one blade in either nostril, and each one of the four fragments of cartilage is seized in turn, separately, and subjected to a twisting motion sufficient to loosen its articulation. In this way all resiliency of the cartilage is overcome, and on passing a finger into the previously stenosed naris it will be found that all resistance has disappeared and the finger can be easily carried through into the posterior naris. If it is not perfectly free, the Adams' forceps should be re-introduced, and the refractory fragment subjected to the same process as before. If the resiliency of the cartilage is not thoroughly destroyed the object of the operation will be defeated.

"The amount of traumatism capable of being borne by the septal cartilage of the nose without untoward effect is simply astonishing, and for that reason one need not be timid about attacking it with vigor.

"When the previous step of the operation has been satisfactorily completed, one of the patterns of vulcanite perforated nasal tubes devised by Asch is then inserted in the formerly obstructed naris. Care should be used, in choosing a tube, to see that it is sufficiently large to hold the septum in the position desired, and, at the same time, it should not be of such proportions as to cause painful and uncalled-for pressure. A tube so large that it requires any considerable amount of force to place in position will surely cause an intolerable degree of pain to the patient when consciousness is regained, whereas one of a proper size will be worn without the slightest discomfort.

"After the introduction of the tube hemorrhage ceases, and the patient is put to bed for thirty-six or forty-eight hours. Twelve hours having elapsed since operation, the nasal chambers are irrigated with a warm borated solution at intervals of two hours; the temperature is taken three times daily, and a rise of from one-half to one degree is sometimes observed on the first and second days. The tube is removed at the end of the third day, the nasal fossæ are sprayed with a ten-per-cent. solution of cocaine to shrink the soft parts, and a thorough cleansing is given with a gentle alkaline spray.

"Usually there is considerable swelling of the intranasal tissues, but the tube is readily reintroduced, and the patient allowed to go about his usual pursuits; he should be seen every other day for some time, and after the first week be instructed to remove the tube himself, morning and night, for cleansing purposes. The tube should be worn for at least six weeks to give an opportunity for the thorough union of the parts.

"Inspection of the intranasal conditions for the first week after operation is apt to be somewhat disheartening to the operator, from the fact that there is a good deal of inflammatory reaction of the soft parts, and the overlapping of the segments of cartilage causes a decided impairment of the caliber of the naris. However, an occasional cleansing and spraying of the membranes with a solution of oil of eucalyptus in fluid albolene, and the mild pressure exerted by the nasal tube, soon induce an absorption of the redundant tissues.

"If there is an enormous ecchondrosis over the apex of the convexity, it may be advisable to saw it off either before or at the time the septum is fractured under ether; thickening to a moderate degree at this point will not require an operation for removal, but will be dissipated by the presence of the tube.

"The special instruments devised by Dr. Asch are an undoubted aid to the proper performance of the operation, not only allowing a quicker and neater execution of it, but a much more accurate placing of the incisions.

"Still, if one has not the instruments at hand, it may be done with a bistoury (using a finger in the patent nostril as a guide to the length of the incisions) and an Adams' septal forceps. In selecting an Adams' forceps, one with blades not more than an inch and a quarter in length, and that do not tend to converge at their distal ends, will be found most useful in grasping the fragments of cartilage."

Irregularities of the Bony Septum.—It rarely happens that the portion of the nasal septum composed of bone and formed by the vomer posteriorly and the perpendicular plate of the ethmoid superiorly, participates in the marked deflections that occur in the cartilaginous one with which it articulates anteriorly.

Deflections and deformities of the bony septum are generally congenital or the result of inflammatory processes, and are rarely due to traumatism. Fractures of the perpendicular plate of the ethmoid bone do happen as the result of severe blows on the nose, but the vomer mostly escapes the force of the concussion, as its anterior margin does not extend so far forward as do the other bones of the face.

Irregularities of the vomer can usually be overcome by the use of the saw, but if there is complete bony occlusion of the posterior nares it may be removed by tunnelling with the electro-trephine. The electro-trephine is a dangerous instrument in the hands of any one who is not an experienced operator in the nasal regions; it has great penetrative powers and works so rapidly in destroying tissue that unless one knows the anatomy of the parts thoroughly, one may do irreparable injury. In using the trephine its sphere of action should be

limited to the lower half of the vomer, and the cutting edge should always be directed backward and slightly downward, otherwise the cavity of the skull may be perforated.

Operations on the bony septum should be confined to that which can be done with the nasal saw or the electro-trephine. Fracturing the vomer with powerful forceps has led to fatal results by fissuring the walls of adjacent sinuses and causing uncontrollable hemorrhage at remote points from that at which the force was applied.

Abscess of the Septum.—One other condition of the septum, that of abscess, causing a temporary occlusion of the nose, should be mentioned, as it is capable of producing a very great and life-long deformity of the external nose. Abscess of the septum is usually the result of a direct injury to the nose (creating an extravasation of blood in the tissues lying between the cartilage and the mucous membranes), but it may appear as a late manifestation of syphilis.

There is no other affection likely to be mistaken for an abscess of the septum, for the patient gives, as a rule, a distinct history of traumatism, and when the nasal fossæ are inspected they are found to be occupied by a smooth, rounded, fluctuating, and painful tumor, springing from the fore part of the cartilaginous septum. The dorsum of the nose is likely to be reddened and swollen, and the patient complains of much localized pain of a throbbing character.

The ordinary treatment of an abscess, early incision and drainage, will prevent, in most cases, a great destruction of the cartilage and a consequent falling in of the nose. If the abscess is of syphilitic origin, constitutional medication is begun as soon as the pus has been evacuated.

Nasal Myxomata.—Nasal myxomata, or polypi, are in the majority of cases not true tumors, but hyperplasias resulting from inflammatory processes of the mucous membranes and the surrounding tissues.

There is perhaps no form of nasal stenosis so complete as that occasioned by the unrestrained growth of polypi in an old case in which both chambers are involved. In about 50 per cent. of all cases of polypi the growths are bilateral, and from their gelatinous composition and because they have their origin mostly from the upper part of the nasal fossæ (springing from the middle turbinated bodies and the middle meati) they will, if unmolested, truly fill the nose to overflowing.

From the fact that they can so entirely obliterate the breathing and drainage spaces, nasal polypi are capable of producing more serious damage to the immediate structures of the nose than any other benign pathological condition found in this region. As a result of the complete plugging up of the nose, we may have a purulent inflammation of the frontal, maxillary, sphenoidal and ethmoidal sinuses with destruction of their walls by necrosis.

Other symptoms of polypi than those ordinarily following an incomplete nasal stenosis are excessive sneezing, bronchial asthma, facial neuralgia, deafness, and a peculiar deadness of tone in the speaking voice that is pathognomonic of the disease, all of which conditions are aggravated during wet weather, on account of the hygroscopic peculiarities of these growths.

Nasal myxoma, although usually multiple in number, may manifest itself as a pendulous enlargement of the anterior end of the middle turbinated body, or most rarely from the septum or inferior turbinated body, in which case the symptoms are slight, and beyond a feeling of stuffiness and the sensation of a valve clicking in the nose on inspiration or expiration, the patient has little cause for complaint. In the majority of cases which we observe, however, the conditions are exaggerated even to the point where polypi are seen to be protruding from the anterior and posterior nares.

So far as the treatment of nasal polypi is concerned, it matters little how many there may be, except in regard to the time necessary for their removal. Most operators rely on the use of the cold-wire snare for the ablation of these growths, having discarded the idea of trying to shrink them up by the use of astringents or of destroying them with caustics. Another method that has rightly been relegated to the past is the removal of polypi by the indiscriminate use of cutting or tearing forceps, as it is an unscientific and inaccurate procedure, and often results in permanent injury to the nasal fossæ by causing extensive cicatricial adhesions.

Of the many patterns of cold-wire snare for use in the nose, the speaker prefers the one designed by Sajous, which is a modification of the well-known Jarvis instrument. This snare is very light in construction, easily handled, and is armed with a wire loop about three inches in length, which is sufficiently large to meet any requirements for the removal of nasal myxomata.

The principal object to be attained in an attempt to remove a polypus is to get the whole tumor with its pedicle and site of attachment, and this is best accomplished when the growth springs from the middle turbinated body in the following manner: The nasal chamber is anæsthetized as well as may be by the use of a spray of a ten-per-cent. solution of cocaine; the loop of the snare having been compressed laterally so that its short diameter measures about one-half an inch, is then introduced into the nostril, parallel with the plane of the septum, and carried back in this position until the tip of the instrument touches the anterior border of the growth, when the loop is made to turn and encircle it by manipulation of the shaft of the snare. The growth being surrounded by the loop, the latter is now carried high up by a slight jiggling movement until the tip of the snare is pressed firmly against the anterior end of the middle turbinated bone. The loop being in a correct position, it is drawn home rapidly by turning the milled-nut located at the proximal end of the handle, but during this process great care should be exercised to keep the beak of the instrument pressing firmly against the turbinate, otherwise the tendency will be for the loop to slip forward and the result will be incomplete.

If the operation has been properly performed the polypus will have been brought away whole, and with it the mucous membrane covering that area of the middle turbinate. Indeed, it is even desirable to include in the removal a portion of the spongy end of the bone itself, as it frequently is the seat of a necrotic process.

The operation as described should be repeated as often as necessary to clear the nasal chambers. It is not advisable to subject the patient to too much pain and nervous strain at one time, and when the nasal fossæ are completely blocked with polypi it is better to extend the operative work over a period of half a dozen sittings.

Although much has been written and said to the contrary, the removal of multiple nasal myxoma under cocaine anæsthesia is always a somewhat painful operation. This is explained by the difficulty one has in placing the cocaine on the surface

to be cut, which is high up in a fossa that is densely packed below with the growths.

Again it is the custom of the writers of textbooks to advise a slow operation with the cold-wire snare, they claiming that by extending it over a period of half an hour or more for the removal of one mass of polypoid tissue, the operation is made a bloodless one. The speaker's views are that the small amount of blood lost in the rapid excision of polypi is of minor importance, and as the agony is sooner over, it is to the best interests of the patient to complete the operation as speedily as possible.

Neither is it recommended that the region from which the polypi spring should be touched with the galvanocautery, or caustics, to prevent a recurrence of the growths. The surgeon's main reliance should be placed on his having done a sufficient number of thorough cutting operations to have removed the diseased membranes, which will, in time, be replaced by cicatricial tissue from which polypi will not grow.

313 Madison Avenue.

CASES OF MORPHINISM IN WHICH THE DRUG WAS IMMEDIATELY WITHDRAWN.

By MARGARET S. HALLECK, A.B., M.D.,
BEDFORD STATION, N. Y.
NEW YORK STATE REFORMATORY FOR WOMEN.

Only a few years ago students were taught that the morphine habit must be broken off by degrees, and that its cure was always attended by untold suffering. Current textbooks still teach that severe symptoms will follow the sudden withdrawal of the drug. Being so fortunate as to have my patients in a hospital where I could completely control their treatment and watch them every hour if necessary, I determined to try the experiment of cutting off the drug at once.

As each patient came under my care I endeavored to win her confidence and to make her feel that she and I together would carry the day. I told her frankly that no morphine would be administered, but that she would not be allowed to suffer much. Each one expressed a desire to be cured of her habit. Hypnotism was not resorted to, but suggestion and a great deal of personal interest were freely used all through the treatment.

Case I.—Came under treatment May 24, 1901. She was an American, aged twenty-four years, weighed ninety-nine pounds. She claimed she contracted the habit while under the doctor's care for a broken leg. This statement is somewhat unreliable, as her first method of taking the drug was, in fiend parlance, "hitting the pipe." She was taking six to ten grains of morphine daily besides smoking a dollar's worth of crude opium. This being my first case, I waited to see what would happen. She sent for me in the evening and was evidently suffering greatly. Her pupils were dilated, she was vomiting, in a cold perspiration, extremely nervous and said she ached all over.

I gave her strychnine sulphate $\frac{1}{60}$ of a grain, hyoscine hydrobromate $\frac{1}{200}$ of a grain, codeine sulphate, $\frac{1}{4}$ of a grain, and suggested that she would pass a comfortable night. Water was also freely given.

No one watched the patient during the night. Next morning she complained that she had not slept well, but vomiting had ceased and she was free from pain. She was visited every morning and evening for a week and given the same dose with slight variations. At the end of the week she left her room and did light housework. Still somewhat nervous, her pains gone, and appetite good, she kept about. Strychnine $\frac{1}{60}$ to $\frac{1}{30}$ grain was given for another week. Then all treatment was stopped. In six months she gained thirty pounds. She remained with us a year, and was exceptionally well the whole time. She had been out now eight months, and we have heard from her or her parents each month. So far she has not relapsed.

Case II.—Came under treatment June 19, 1902. German girl, aged twenty-three years. Came to New York City with her parents when nine years old. Ran away at the age of fifteen years with an older girl, who took her to Chinatown. Here she learned to smoke Hop, and the habit mastered her for eight years. When she came to me she was smoking from one dollar to one dollar and a half worth daily.

Patient was emaciated, pupils dilated, pulse slow, no appetite, constipated, muscular tremors, tongue coated, nauseated, and in pain.

She weighed 109 pounds. She was put to bed and given strychnine sulphate $\frac{1}{60}$, hyoscine hydrobromate $\frac{1}{100}$, codeine sulphate $\frac{1}{4}$ of a grain.

June 20, A.M.—The same, except one-half the quantity of hyoscine. This was repeated on June 21 and 22. June 23, no medicine was given. I found her dancing in the evening and she told me how well she felt. June 24 and 25, the same treatment as on the 20th. July 3, hyoscine hydrobromate $\frac{1}{200}$, was given simply for variety. July 5, 6, 8, 9, 11, 18, 19, 21, 22, 26, and 28 she came to the office and was given one tablet of strychnine $\frac{1}{60}$. Aside from cascara tablets and water, this is all the medicine she has had. To sum up, this patient had in all ten tablets of hyoscine $\frac{1}{200}$, twenty-one of strychnine $\frac{1}{60}$, and seven of codeine $\frac{1}{4}$.

She is still with us and a good member of society. Her present weight is 142 pounds. She says she has no desire for the drug, and when I interviewed her a week ago she told me the same story of her former life that she did when she entered.

Case III.—An American, aged twenty-nine years. She contracted the habit in a New York City hospital, where she was being treated for a broken wrist. She had taken morphine ever since in increasing doses, that is, for ten years. When she came under my care she was taking twelve grains daily, and said this has been her average daily dose for the last five years. The general description of Case II applies here also.

August 10 she was put to bed and given strychnine, hyoscine, and codeine, one tablet of each. August 11 same treatment. August 12, strychnine only. The first day's treatment was repeated daily until the 21st; after this she had strychnine sulphate $\frac{1}{60}$ for six days. The fifth, sixth, and seventh days of her treatment she suffered from nausea.

I did not increase her medicine, but visited her oftener, saw that she drank water, and suggested that the vomiting would relieve her more quickly. The ninth day she was lonesome and begged to be allowed to leave her room. After that time nothing was given her but the tablets above noted. To-day she is the picture of health, and weighs 190 pounds. She claims to have no desire for morphine, her feeling is rather one of aversion.

Case IV.—An American, aged twenty-four years. She was taught the habit by an older woman. She had taken morphine hypodermically for the last seven years. Last winter her daily dose was from fifty to sixty grains, and in addition she had taken cocaine for a year. Last spring she entered Bellevue three separate times to be cured of her habit, but had relapsed each time. She had, however, reduced her daily dose somewhat. Patient was very

emaciated, weight 90 pounds, pupils dilated, nervous, pulse regular but slow, constipated, body covered with lesions left by the hypodermic. She was put to bed November 24 and given the following treatment: One tablet each of hyoscine, strychnine, and codeine at noon and at eight o'clock in the evening.

November 28, same treatment except a cathartic. November 29, same in the morning, but two hyoscine tablets in the evening, as she was nervous and wanted to sleep. November 30, had not slept well, no pain, ate voraciously. At 9 A.M., one hyoscine, one strychnine, one codeine. At 7 P.M., two hyoscine. At 9 A.M., one hyoscine. December 1, had slept well; A.M., one codeine and one strychnine. P.M., one hyoscine and two codeine. December 2, no medicine. December 3, one hyoscine and one strychnine. December 4. one hyoscine, and on the 11th one strychnine tablet. Since that time she has not asked for or taken a bit of medicine. She eats well, sleeps well, looks well, and has gained in weight, her present weight being 114½ pounds, a gain of over twenty pounds in six weeks.

CASE V.—Mexican, aged twenty years, weight ninety-two pounds. She had peritonitis at the age of thirteen years, following childbirth. Her morphine habit dates from this time. At first she took it by mouth, then smoked it for three years, but for the last three and one-half years she has taken it hypodermically. For the past year she has also taken cocaine by inhalation, averaging about six grains daily. Her physical description is so like the preceding that it need not be repeated. The two patients entered together and were treated exactly alike, except that this one had one less tablet of hyoscine and strychnine. The present weight of this case is 116 pounds, a gain of twenty-four pounds in six weeks.

Cases one and two were smokers for from three to ten years.

Case three had taken it for ten years by mouth.

Cases four and five had taken it by mouth and hypodermic for seven years.

Case four, who had been treated in a city hospital, assured me that it would be impossible to cut off all morphine at once in her case; that when she had been treated before the dose had been gradually reduced, and that although she had been given bromide and sedatives every few hours she had suffered agonies and had even been restrained in bed. She was treated here just one week, and at no time did she complain of anything except pain in the back and nervousness. She was more surprised at her quick and painless recovery than she could express. The same treatment cured all cases in practically the same time. Case one has been out since last May and has not relapsed. The others are still with us, and are among our healthiest inmates. They are free to call for treatment at any time; they all say they need nothing. They seem to have no craving for anything. Their appetites keep excellent and all bodily functions go on normally and unaided. Friends who have not seen them for a few weeks hardly recognize their bright, well-nourished faces. Strychnine, hyoscine, and codeine certainly form a perfect antidotal combination and one which works quickly. Morphine, as we know, depresses the nervous system, reduces metabolism, hinders the action of the liver, finally paralyzes the vasomotor centers, and lessens all secretions. Strychnine, on the other hand, stimulates all functions, increases the appetite, and while doing this it is eliminating the morphine. Nausea, restlessness, insomnia, and pain are cared for by the hyoscine and codeine. It seems reasonable that this combination should cure in time, but the celerity of cure, with no suffering to speak of, and the very small amount of medicine used, is certainly remarkable. These cases may relapse, but it will not be because they are unable to fight the habit.

BRONCHOPNEUMONIA.*

By JOSEPH N. STUDY, M.D.,
CAMBRIDGE CITY, IND.

THIS disease usually affects young children and those who are under five years of age. It is said to attack often elderly subjects at the opposite extreme of life, and frequently occurs in persons suffering from tuberculosis and others who are constitutionally weak. The subject of this article applies wholly to bronchpneumonia as it occurs in children. If we can be guided by some of the more able writers upon the diseases of children, not longer than a quarter of a century ago, then the above title may appear as a new name applied to an old and well-described affection, namely, capillary bronchitis. This condition was well described by J. Lewis Smith in his careful, painstaking manner, and, under the subject of prognosis, he speaks of its being one of the most fatal diseases of early childhood, especially in those under one year of age, and more especially if complicating or following any of the acute infectious or wasting diseases. Complicating whooping-cough, it was said to portray one of the saddest scenes—a child cyanosed and battling with a paroxysm of coughing. The mortality was invariably high.

This older name, capillary bronchitis, from both a clinical standpoint and the pathological findings, seems to embody completely all the symptoms and conditions described under the more modern appellation of bronchopneumonia. J. Lewis Smith says of capillary bronchitis that the disease begins primarily in the larger tubes and extends to the small and smallest air-cells, while Osler tells us the affection invariably begins in the smaller tubes and in the air-cells, extending thence to the larger tubes. The two conditions, however, combine one affection which is found in the lungs of children dying from this disease, namely, an inflammation involving the mucous membrane of the bronchial tubes, extending into the air-cells and most frequently also into the alveoli and connective tissue. Collapse of a lobule is often the result, and the air-cells and tubes contain mucus and pus cells, while section of lung may show gray or red hepatization.

It would seem highly improbable that so serious a condition as a severe attack of this disease could occur without involving all these structures to greater or less extent.

This disease occurs at all times and seasons. Sudden changes of atmosphere renders the late fall, winter and early spring months especially productive of this affection. The older authorities placed much stress upon the belief that these atmospheric changes, with perhaps a lowered vitality from various causes, was sufficient to produce in children these characteristic phenomena. Modern medicine comes to our aid and suggests that the pneumococcus lanceolatus is the cause of pneumonia, and consequently the sole, or leading, factor in the production of the disease.

In the lobar variety of pneumonia, which we are not, however, considering, Netter found this bacillus present in 65 per cent. of all cases. Curry, in the *Journal of Experimental Medicine*, found the bacillus present in thirty-two consecutive cases. In bronchopneumonia the bacillus has not so constantly

*Read before the Wayne County (Ind.) Medical Society.

b:en found, but it is, nevertheless, found with such frequency as to cause the belief of the bacteriologist, that this is perhaps the sole or leading cause of all bronchopneumonias. This relative absence of the bacillus—if it be true that pneumonia is caused only by the bacillus known as the micrococcus lanceolatus —awaits the explanation of the bacteriologist.

However, the somewhat ancient belief that has well stood the test of many years past, that atmospheric conditions and a lowered vitality, with perhaps something born in each individual, which we will, for convenience, call susceptibility, have, in fact, something to do as etiological factors in producing the disease.

The diagnosis of bronchopneumonia in many cases is not especially difficult. Perhaps one of the most frequent mistakes is made in differentiating this affection from a simple acute bronchitis. In a given case in which the bronchial and vesicular auscultatory sounds have passed beyond the limits of which an ordinary bronchitis should approximate, coupled with considerable increase of temperature and marked accelerated breathing, and increased heart action, should leave but little doubt of the condition present. From an acute lobar pneumonia the exaggerated bronchovesicular murmur usually involving both lungs, in one. In the early stages of the other, the crepitant rale, and later, partial or complete absence of the normal vesicular murmur, and flatness and dulness at times in the percussion note, and its usual occurrence in one lung, should not be very hard to distinguish one from the other. The early stages of pneumonia and meningitis might present some points common to either affection, and when we remember that one person in seven dying from pneumonia of the lobar variety has a complicating meningitis, this condition should not be lost sight of.

It should not be forgotten that in many conditions in childhood attended with fever the respirations are almost invariably accelerated, and auscultation will frequently reveal abnormal sounds, which may take more than one examination to determine the conditions present. Age in this disease gives some aid. Of all pneumonias occurring under the fifth year, a large preponderance are bronchopneumonias, and under one or two years of age lobar pneumonias rarely occur. The occurrence simultaneous or following one of the acute infectious diseases, strongly suggests bronchopneumonia.

I have frequently, in this disease, auscultated the lungs of children to find at my next visit changed conditions to other and more remote portions. There is generally a marked increase of temperature, often reaching to 102° to 105°, most frequently in the late afternoon and night, although my personal observation leads me to believe that this temperature curve does frequently vary. There is often a maximum temperature in the morning and sometimes a complete remission of the fever. The pulse is usually very fast in severe cases, often 120 to 140 or 180 or more beats per minute. The respirations are sometimes as rapid as fifty to ninety per minute.

The respiratory pulse ratio characterizes pneumonia in children from all other affections. Cough is frequently present, but in some very severe cases it is seldom noticed. Expectoration is rarely seen as a part of this affection. In severe and fatal cases, the skin assumes an ashen cyanosed condition, resulting from an accumulation of carbon dioxide in the blood acting upon the nerve centers.

In the physical examination of these little patients the stethoscope is of incalculable value, and all portions of the thorax, lungs, and heart can be quickly and accurately auscultated, even in the most irritable child, without prolonged or unnecessary exposure. The posterior portion of the lungs and infrascapular region should invariably be examined. These examinations should be made each day at least. This disease so frequently attacks more than one member of the same household, that its contagiousness may reasonably be looked upon without much, if any doubt.

The treatment in these cases, when it can be carried out, should be first to place the child in a large and well-ventilated and lighted room, at as near a uniform temperature as possible—65° to 68°. The chest of the child should be well protected with cotton or wool clothing. Turpentine and lard, or camphorated oil in sufficient strength, rubbed over the entire thorax one or more times a day, is an admirable local application. The above will meet all the requirements that any local measure can accomplish. This affection is one which the writer believes is self limited, and it is questionable if any drug or drugs ever cut short or aborted the affection. But it is believed that drugs may have a very beneficial effect to meet certain indications as they present themselves. If the bowels are not sufficiently active, calomel in small doses every one or two hours should be given until they are well moved. I seldom give much quinine in this disease. Its use is of a doubtful utility. In a majority of cases, if there is cough or marked restlessness, I think opium, in small doses, especially in the early part of the affection, does good in securing rest, relieving pain, and quieting cough. The smallest dose that will meet the indications should always be administered. I usually meet this indication with paregoric or liquid dover's powder, combined sooner or later with arometic spirits of ammonia or ipecac, withdrawing or adding either, as may be indicated. Carbonate of ammonia should seldom be given, on account of its nauseating pungent taste, the good effects of which are found in its less objectionable brother, the aromatic spirits. If the temperature is high—say, above 102'—I seldom give the coal-tar derivatives. When I do, it is not for any prolonged time, and I usually give small doses of acetanilid, combined with sodium, salicylate, and caffeine citrate.

In its stead I have given general sponge baths at a temperature below the normal body temperature, with good results. In some severe cases in which there was considerable fever, rapid breathing, and cyanosed condition following, a warm tub bath with mustard added to the water has acted well to relieve this condition.

I have recently treated a delicate child with a severe bronchopneumonia, in which liquid peptenoids combined with creosote, acted well. From the recent good reports from the use of creosote in pneumonias of all kinds, I should expect good effects to be obtained from the use of carbonate of creosote in bronchopneumonia. There are some cases in which alcoholic stimulants would evidently be indicated in some stage of the affection, but their routine administration should be discountenanced. When heart and respiratory stimulation have seemed indicated, I have administered strychnine with marked good results.

Nutrition should be maintained in children not nursing the breast, by milk, egg, albumen or meat broths, administered at regular intervals. Water should be administered freely to all these little patients, and its administration, at regular intervals, insisted upon. The face, mouth, and lips should be kept clean with simple warm water.

While this disease has been characterized by the

authorities as one with a mortality reaching from 25 to 50 per cent., my own personal observation has been that these little patients get alarmingly ill, which they really seem and are, but usually after from one to three weeks—rarely six weeks—almost all have made a good recovery, and without any chronic sequela following.

THE *X*-RAY AND THE FINSEN LIGHT IN THE TREATMENT OF LUPUS.

By A. D. ROCKWELL, M.D.,
NEW YORK.

The beneficial effects of both the *x*-ray and the actinic rays of light upon superficial malignant growths and ulcerative processes have been so very positively established, that the report of a single case of lupus is of no great moment. An interesting point, however, in a case recently treated, is the fact that both the *x*-rays and the Finsen light were utilized in the treatment, opening up the question so frequently asked as to which of the two is the better and more effective method. It cannot be expected that a positive answer can be given this question at this stage of our experience.

The actinic rays, which are the only efficient rays of light in the treatment of malignant or tuberculous skin affections, possess one great manifest advantage over the *x*-ray, namely, their more benign action. It is true that light radiance, like its fellow, the *x*-ray, causes both chemical changes and fluorescence, as well as dermatitis and pigmentation, but the dermatitis, the result of light, is soon produced, and undergoes rapid resolution, while *x*-ray burns are both slower to develop and far slower to heal. So far, then, the light is to be preferred to the ray.

On the other hand, there seems to be no question that the curative effects of the *x*-ray in lupus and other skin affections, follow more rapidly than those of light, while with improved technique *x*-ray burns may in time become an almost negligible quantity. The *x*-rays and the actinic rays of light do not differ so much in kind as in degree—in the frequency and intensity of their vibrations. Their therapeutic effects are therefore very much the same. They cure the same diseases.

This question of differences in degree rather than in kind applies to all the various electric modalities. There are few pathological conditions susceptible of resolution by one form of electricity that cannot be influenced in greater or lesser degree by some other of its manifestations. The analogy holds good in the consideration of psychical, and other physical forces, and in the use of drugs.

In the case to which allusion has been made—a case of lupus vulgaris of the chest of long standing—the Finsen light had been used with a measure of success. Changes that were distinctly beneficial were observed up to about the fifteenth treatment, but thereafter, although there were some thirty more exposures, no further improvement was appreciable.

Some two weeks after abandoning the light treatment the patient began treatment by the *x*-rays, and with results that were most satisfactory, finally ending in complete recovery after some forty-five exposures, administered through a period of four months.

The question arises whether in other cases this experience might not be reversed, the chemical rays of light succeeding after the failure of the *x*-rays. It is reasonable to believe that here, as in other therapeutic measures, one form of treatment may effectively supplement and reinforce the other. Idiosyncrasy is again something that must always be reckoned with in therapeutic differentiation. Susceptibilities vary in their relation to *x*-ray effects quite as positively as they do in their relation to electric modalities. In some persons an active dermatitis is readily excited, while others may undergo repeated exposures without the slightest irritation. I recall one patient who was so susceptible to *x*-ray influence that it was quite impossible for her to continue treatment. Even when no appreciable dermatitis was evident, the slightest exposure caused an unpleasant sense of burning and itching, with an irresistible desire to scratch. The Finsen light, which she subsequently tried, had no such unpleasant effects, and greatly benefited her. The question of differentiation between the use of the actinic rays of light, and the *x*-ray is an interesting and important one, in which the personal equasion must often be the determining factor.

25 East Forty-fourth Street.

THE TREATMENT OF RING-WORM.

By GEORGE THOMAS JACKSON, M.D.,
NEW YORK.
CHIEF OF CLINIC AND INSTRUCTOR IN DERMATOLOGY, MEDICAL DEPARTMENT OF COLUMBIA UNIVERSITY.

Ring-worm, like the poor, we have always with us. No matter where a doctor's work may lie, whether in the city or in the country, if he is in general practice he will sooner or later be called upon to treat ring-worm. There are few diseases of the skin easier to cure than ring-worm of the so-called non-hairy parts of the body. Sulphur, iodine, salicylic acid, mercury, ony one of these in ointment or lotion will cure it. Indeed, most of them are not brought to the doctor, but cured by means of domestic remedies. While it is easy to cure ring worm of the non-hairy parts, it is difficult to cure ring worm of the scalp and beard, specially the former. In many communities a case of ring-worm of the scalp will float around from one doctor to another, and will persist in spite of their best endeavors. No conscientious physician will promise them a speedy cure. If the patient is well in six months or a year the doctor can congratulate himself upon his success.

To a certain extent this is true of ring-worm of the beard, barber's itch. While it is by no means as intractable as is ring-worm of the scalp, still six months is often necessary for a cure under most methods of treatment.

The reason for the intractability of ring worm of the scalp and beard is that the fungus grows down into the hair follicles, and it is very difficult to make our well-recognized antiparasitics penetrate to the seat of the trouble without damaging the skin.

It is not my intention to detail the many methods of treatment with which all are more or less familiar, but to commend one that I have used for some years with excellent effect, and to ask that it be given a trial.

In looking for an excipient that would penetrate easily and be bland, goose grease occurred to me as probably just what I wanted. Many who have been brought up in the country will remember how our mothers used to rub our throats and noses with goose grease when we had a cold, in the belief that "it would loosen up the phlegm."

I have found it better than I had hoped for, and if a drachm or more of the crystals of iodine is added to the ounce of goose grease, it will make a most effective remedy for ring-worm.

At the Vanderbilt Clinic, New York City, where we have many cases of ring worm, this preparation has been used extensively for two or three years,

almost exclusively after the first few months, when it was found to be more efficacious than other remedies. It is to be applied twice a day until it produces reaction, as shown by a little swelling of the patch. Then once a day will be sufficient. In two or three weeks the hair falls out of the patch, and it becomes bald like a patch of alopecia areata. After a time the hair grows again, and the patch is well. The first applications are apt to be a little painful for a few moments, but after that, even little children do not complain of pain. No epilation is necessary.

When used on the bearded portions of the face the applications are more painful than when the scalp is the part treated. If much reaction with swelling is caused the use of the remedy can be suspended for a few days and a salicylated oil of 3 per cent. strength can be used. As soon as the reaction subsides the remedy should be used again. The result in this form of ring-worm is remarkable. A few days ago I asked Dr. Dade, who has charge of one of the classes for men at the Vanderbilt Clinic, how long it took to cure barber's itch with the preparation. He said just three weeks, as he had noted in many cases. This coincides with the results I have had in private practice. Just one word of caution. Be sure to obtain the genuine article. I am told by those who should know, that the goose grease dispensed by many druggists has never seen a goose, but is manufactured of several fats which, like goose grease, melt at low temperature. There are some good samples on the market. The finest variety is expensive, as it is made from the fat of uncooked geese.

Occasionally an obstinate case will be met with that will not yield to this treatment. In such a case I have had good results from the use of an ointment composed of from half a drachm to a drachm of croton oil to the ounce of sulphur ointment. After a few days it will cause a good deal of dermatitis and convert the patch into a perfectly bald one. Eventually the hair grows in again and the disease is cured.

15 East Twenty-ninth Street.

Actinomycosis of the Lungs.—Actinomycosis in man is not so rare as it has been generally supposed. That it should have been considered so is, according to Prof. J. K. Spijarny, mostly due to the difficulty of its diagnosis. Actinomycosis of the lungs occurs in about 20 per cent. of these cases. The fungus actinomyces bovis enters the lungs either directly during inspiration, or indirectly through the alimentary system. There are two forms of the disease, viz., the deep and the superficial; the latter is of no significance; the former deeply affects the parenchyma of the lungs with subsequent destruction of tissue. It consists of three stages: (1) The formation of foci of infection with destruction of the surrounding tissue, formation of connective tissue leading to adhesions, compressions, etc. (2) The necrotic process approaches the surface of the lungs, affecting the pleura, resulting in exudations, adhesions, etc., and finally spreads upon the thoracic wall. Sometimes it spreads to the diaphragm, or to the pelvis, affecting the internal organs. At last a swelling appears on the thoracic wall, within which softened spots are soon formed, and fluctuation follows. (3) The third stage is characterized by the opening of the swelling and the formation of fistulæ. Metastases occur in different organs, pyæmia develops, and finally death follows after some months or years from exhaustion, or the involvement of an important organ.

Actinomycosis of the lungs in its general course strongly resembles pulmonary tuberculosis, in both its physical and clinical characteristics, but the constant absence of tubercul· bacilli, and the presence of actinomycotic fungi in the sputum clearly indicate the character of the disease. Very characteristic is also the swelling appearing on the chest, from the softened parts of which pus containing actinomycotic fungi may be withdrawn with the aspirator. Sometimes the general course of the disease resembles chronic pyæmia, and only the examination of the exudate of the foci of infection clears up the diagnosis. The prognosis is unfavorable. Regarding the treatment, Karewsky advises the thermocautery for the removal of affected parts. Lakowsky advises the Paquelin cautery. In all severe cases removal of affected parts, either with knife or cautery, is necessary; in milder cases, especially at the beginning of the disease, Rasumousky and Berazol advise either K. T. alone in very large doses, or K. T. combined with some slight surgical procedure, aspiration, partial resection, etc.—*Meditsinskoye Obozzienye.*

Ocular Headaches.—Sydney Stephenson says that the cardinal diagnostic point of ocular headaches is that pain, whatever its exact site and nature, is brought on, or at least rendered worse, by using the eyes. He reports a number of cases which illustrate the following practical points: (1) That it is the low degrees of hypermetropia, and especially of hypermetropic astigmatism, that have the greatest tendency to give rise to headaches. (2) That in such cases the sight at the distant types is usually normal or even better than normal. (3) That it is of vital importance to correct even such low degrees of astigmatism as 0.25, D or 0.50 D. (4) That the greatest discomfort is likely to be met with when astigmatism is asymmetrical as regards the two eyes or when the axis of the cylinder is horizontal or nearly so, instead of being, as is the rule in hypermetropic astigmatism, vertical or nearly vertical. (5) That the ametropia must be estimated under the influence of a cycloplegic, as atropine or homatropine. The relief to the pain obtained during the use of these agents is sometimes very marked. When this is the case one may safely promise that the headaches will be cured by glasses, although the converse is not invariably true. We should expect asthenopia to be marked: (1) In patients who are recovering from some general illness; (2) in those of neuropathic disposition; (3) in those of sedentary habits who use the eyes for long periods; (4) in persons of good social standing and of more than ordinary education, and (5) in children and those who belong to the female sex.—*Medical Press and Circular.*

On Certain Forms of Menstrual Suffering, and the Action of Permanganate of Potash Therein.—Wm. Stephenson uses the term menstrual suffering, because it embraces all forms of derangement of the function, does away with the limitation of such terms as amenorrhœa, and includes affections of distant organs associated with the rhythmic changes of the menstrual cycle. The writer's experience of nearly twenty years is that this drug gives more direct and reliable results in menstrual troubles than any other. He describes various cases, one of which had suffered from amenorrhœa for fifteen months; another from dysmenorrhœa and vascular weakness with distension of the veins in the leg; a third from dysmenorrhœa, menstrual headaches, distended veins, and eruption on the face; still another had chlorosis at eighteen, phlegmasia dolens at twenty, for four years dysmenorrhœa, menstrual headaches and varicose veins. In all of these cases, permanganate was ordered in the form of pills, gr. ii. ter in die. In the great majority of cases, headaches are amenable to the action of manganese. Sometimes the headaches are of the intermenstrual type. In some cases it takes five, six, and seven months before the beneficial effect is fully secured. It is a mistake to prescribe it as if it were an emmenagogue a day or two only before an expected period.—*The Scottish Medical and Surgical Journal*, January-February, 1903.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

New York, April 11, 1903.

THE PROSPECT OF EXTINGUISHING TUBERCULOSIS.

A SOMEWHAT new theory as to the cause of the spread of tuberculous infection has been started recently. Dr. Alfred Hillier read a paper before the British Society of Medical Officers of Health, on January 9, 1903, entitled "The Prospect of Extinguishing Tuberculosis Based on the Researches of Koch, Flügge, Niven, and Others."

A considerable portion of Dr. Hillier's address was devoted to a comparison of the statistics relating to tuberculosis in England and Prussia since the year 1875. The annual death rate per 10,000 of these countries show that while the English decline in mortality from consumption is fairly constant, the decline in the Prussian death rate is by no means of the same character. In England the deaths from phthisis have been declining since 1838, when they stood at 38 per 10,000, down to the present time, when they are only 13 per 10,000, and this decline, in the opinion of many competent authorities, is associated with, and largely attributable to, the generally improved sanitary conditions and food standards of the working classes. Professor Koch is also of the opinion that the degree of segregation and isolation afforded by the English chest and general hospitals has materially aided in this fall.

In Prussia, whose statistics do not deal with the phthisis rate alone, but with the whole of the deaths from tuberculosis, the only decline—and that is a rapid one—of which the statistics furnish a record has occurred since 1886. From 1876 to 1886, a period during which the English tuberculosis rate was steadily diminishing, the Prussian rate remained stationary at about 31 per 10,000. But in 1887 the drop in the Prussian rate began, and it has continued steadily down to 1900, when it had fallen to 21 per 10,000. In England, during the same period, the drop in the tuberculosis death rate has only been from 24 to 19 per 10,000.

Dr. Hillier believes the phenomenal drop in the Prussian death rate to be due to three chief causes: (1) The discovery of the tubercle bacillus, and the spreading of the knowledge of the infectious nature of phthisis, which Professor Koch says has led to the taking of precautions even among the lower classes in Germany. (2) The greatly improved general conditions of the working classes brought about by the operation of the Workman's State Insurance Laws, the first of which, the Sick Insurance Law, came into existence in 1883. (3) The establishment of sanatoria, although this is too recent a movement in Prussia to have had much effect at present.

But the progress made in England and Prussia, in arresting the spread of tuberculosis, great as it has been, is not nearly quick enough to satisfy Dr. Hillier, who thinks that the scourge can be wiped out in half a generation. And this is what the views of Koch. Flügge, and others, if put into practice, will accomplish, the author thinks. Koch deems that the victim of consumption, who after, say, some months in a general hospital, finding himself rather worse than better, goes home to die, is the most terrible source of further infection. Both Koch and Flügge hold that the minute-drop infection, the microbe-laden spray shed around him by the consumptive in his last stages, is a more potent and virulent factor in spreading the disease than dried and pulverized sputum. Experiments made by Flügge and Laschtschenko seem to prove this most significant point. A series of cases collected by Dr. Beatty at Manchester also appear to support this view.

Consequently, if this be so, strict isolation of patients in the last stages of phthisis is strongly indicated, and Dr. Hillier is sufficiently optimistic to think that if such a scheme were carried out that the disease would be extinct in a comparatively short space of time. However, the opinions of Koch, Flügge, and others are as yet only opinions, and even if, after further investigations, they are proved to be correct, the difficulties in the way of a rigid system of isolation for consumptives in the last stage must be very great—almost, it would seem, insurmountable. Nevertheless, to be able to demonstrate clearly the most fertile source of tuberculous infection would be a magnificent accomplishment on the part of Koch and his co-workers, and most certainly a long step toward extinguishing the disease.

THE ADULTERATION AND SUBSTITUTION OF DRUGS.

MR. BOSTWICK'S Assembly Bill, to amend the Penal Code of New York State by adding thereto new sections relative to the manufacture, sale, adulteration, deterioration, or substitution of drugs, if it becomes law will tend to prevent the increasing and prevalent pernicious custom on the part of manufacturers and druggists of foisting upon the public drugs which are either adulterated or not up to the proper standard. The bill in question requires that all manufacturers or importers of drugs must affix to all packages containing the same a certificate in writing which shall indicate the purity, strength, and genuineness of such drugs and their ingredients, and in case of drugs which are liable to deterioration through lapse of time, said certificate shall furthermore state the date after which such drugs will deteriorate, and after which they shall not be sold, and in all cases said certificates shall state the date of manufacture or of importation, and also the date of the sale thereof. Any manufacturer or importer, druggist or dealer in drugs, or other person who shall sell, offer, or expose for sale, dispense, or give away any drug which shall not have affixed to it or to its wrapper or package, the certificate or certificates above mentioned, shall

be guilty of a misdemeanor, and liable to a heavy fine and imprisonment.

The clause of the bill dealing with substitution reads as follows: "Any druggist or dealer, or other person who shall sell a drug not demanded by the buyer in place of that so demanded, or substitute any drug not required for another, without the knowledge or consent of the buyer, shall be guilty of a misdemeanor and liable to a heavy punishment.

The fact has been obvious for a considerable time that a law of the nature referred to above, is badly needed, not only in New York State, but throughout the whole country. The adulteration of drugs is a very serious matter, and may be placed almost in the same category as that of food. Both are in a way worse than stealing, for whereas filching a man's property only injures him materially, adulterating food or drugs hurts him physically. One affects his pocket; while the others menace—what is far more important—his health.

As to substitution, it has been proved up to the hilt, that the practice is largely resorted to by New York druggists. The custom from every point of view is most reprehensible. The patient, the physician, and the manufacturer are all sufferers by the druggist substituting another drug than that ordered. The patient because he does not receive the therapeutic treatment which the physician judges to be most suitable for his complaint, the physician because the patient does not respond to treatment in the manner anticipated, and the manufacturer because his medicine may gain an undeserved bad name through the substitution of an inferior article. Adulteration of all kinds, whether of food or drugs, and substitution, should be prevented by the strong hand of the law.

CHARACTER STUDY IN THE EXAMINATION OF PERSONS FOR MILITARY SERVICE.

Dr. Franklin Bache Stephenson, Medical Inspector of the United States Navy, presented, at the 1902 annual meeting of the Association of Military Surgeons of the United States, a paper on the above subject, which was published in the *Journal of the Association of Military Surgeons*, January, 1903. The study of man has within recent years received a great impetus, and it strictly accords with the fitness of things that the knowledge of anthropology should be utilized in selecting individuals who are candidates for military service. Dr. Stephenson draws attention to several idiosyncrasies and physical features which mark the type of man, and are valuable in estimating his moral and mental attributes.

"For example," says the writer, "a short, quick step indicates the same traits of mind. A slow, slouching gait does not mean force of character or promptitude in action. A low, narrow forehead does not tell of high moral qualities. The small or retreating chin reveals a very different future from that betrayed by a wide, prominent jaw. From thin, bony fingers we do not infer constitutional vigor. Good proportions among the parts of the head, of the face, and of the entire body, shows excellence in general product. Extremes in form —plus or minus—have the same general origin as the peculiar or eccentric traits of character—mental or moral. A general average of size is prophetic."

The greater part of Dr. Stephenson's paper is taken up with a brilliant review—which appeared in the New York *Sun*—of a book recently published by Dr. Bernard Hollander, entitled "The Mental Functions of the Brain." The object of this book is to show that all the fundamental psychical functions are localized in the brain.

The majority of textbooks describe insanity as a disease implicating the entire brain; all forms of mental derangement are ascribed to an affection of the whole cortex. Dr. Hollander dissents from these views, and attempts to demonstrate in his work that the principle varieties of mental alienation are localized in definite, circumscribed regions, and frequently are in the early stages at least amenable to treatment.

Dr. Hollander is an advocate of the study of phrenology—that is to say, he is a believer in its study as a science, and thinks that, in the hands of men who possess an accurate knowledge of it as such, it might be put to excellent practical use. The works of Dr. Francis Gall, the pioneer of phrenology, are made the text of Dr. Hollander's remarks. He claims Gall's contention, that the shape of the skull harmonizes with the conformation of the brain to be now established by the best modern authorities, and further says that he does not know of a single anatomist who denies it to be the brain which gives the form to the skull. This assertion is supported by quotations from the writings of many well-known authorities. Sir William Flower said in his lectures at the College of Surgeons in 1879: "The skull is a fair index to the development of the brain in its different regions, and ought therefore to be studied," and added that the longer he lived he saw fresh beauty and meaning in every line and configuration of the cranium, and that the fact that he could not recognize particular skulls presented to him as belonging to certain nations, was a proof that there existed certain fixed and uniform laws in regard to them. Professor Alexander Macallister, at the meeting of the British Association held in Edinburgh in 1892, said: "The study of the brain's development shows that the convolutioning of the cerebral hemisphere is primarily due to the connection and different rate of growth of the superficial layer of cells with the underlying layers of white nerve fibers, and that, so far from the shape of the brain being seriously modified by the constraining influence of the surrounding embryonic skull, the form of the soft membranous brain-case is previously molded upon the brain within it, whose shape, however, it may be, to some extent, a secondary agent in modifying in later growth. We have also learned that the cerebrum is not a single organ acting as a functional unit, but consists of parts, each of which has its specific province; that the increase in the number of cells in any areas is correlated with an increase in the size and the complexity of pattern of the convolutions of that area, and that this, in turn, influences the shape of the inclosing shell of membrane, and, subsequently, of bone." Professor J. Ranke stated in 1891 that the differences in the form of the skull are entirely due to the differences in the development of the brain.

Sir William Turner, late professor of anatomy in Edinburgh University, said that the "precise mor-

phological investigations of the last few years into the cerebral convolutions have led to the revival in Paris of discussions in which the doctrine of Gall and his disciples—that the brain is not one organ but consists of many organs—has been supported by new arguments, and the opinion has been expressed that the primary convolutions, at least, are both morphologically and physiologically distinct organs. Finally, is the opinion expressed by Havelock Ellis in *The Criminal*, 1890: "Gall thrust aside forever the credulous fancies of the physiognomists; and he has been described not altogether without reason as the founder of the modern school of criminal anthropology. He was certainly its most brilliant pioneer. . . . Gall studied the brain, sought to differentiate the functions of its various parts and the effect of its varying development on the skull."

Dr. Hollander contends that Gall's observations, crude as they were, have been confirmed by recent experiments and researches, and although aware that the definitions advanced by himself as to certain brain "localizations" may require a great deal more of scientific evidence, nevertheless he ventures, after fifteen years of accumulated research, to formulate as highly probable the following propositions: First, the prefrontal lobes are concerned with purely intellectual operations. Secondly, the temporosphenoidal lobes are in some way connected with the propensities common to man with the lower animals. Thirdly, the parietal lobes and the posterior part of the frontal lobes are involved in the manifestation of definite emotions, while the occipital lobes bear a relation to the domestic and social affections. Further, Dr. Hollander holds that size of brain-mass bears a proportion to the power of manifestation, and that two brains or skulls differing in the regions above mentioned will differ n character accordingly.

The work of Dr. Hollander is of undoubted value. Phrenology is not as yet a science, nor does the author claim this position for it, but he believes that, intelligently studied, the views initiated by Gall will provide a working hypothesis, and that when the theory is better elucidated, its application will be found to be of infinite use in furnishing modern specialists in lunacy the key to many of the mysterious problems of mental science.

Although Dr. Stephenson entitles his paper "Character Study in the Examination of Persons for Military Service," it is rather an exploitation of Dr. Hollander's development of Gall's opinions. Incidentally, of course, if, as a result of investigation, the seal of definite proof be set upon this theory, its use in choosing recruits for the army will be plainly apparent. At present, however, the matter is one which chiefly concerns alienists, and it must be borne in mind that the question is still *sub judice*.

Heredity of Mental Diseases.

The belief, once universally held, that a very large number of diseases were more or less directly inherited has died out. Indeed, the influence of heredity, so far as the occurrence of disease is concerned, is almost entirely denied. With regard, however, to mental disorders, in the opinion of experienced alienists, the fact has been clearly demonstrated that heredity is an important factor n the production of aberrant mental traits. The *London Hospital* February 14, deals with statistics collected by Dr. J. Wiglesworth, Medical Superintendent of Rainhill Asylum, who investigated the family history of a series of cases with a view to answering some of the questions which suggest themselves in connection with heredity and insanity. The ground covered by Dr. Wiglesworth is wider than would be convenient to discuss here, so that it must suffice merely to touch upon one or two points. The inquiries referred to, and which were incorporated in articles contributed by Dr. Wiglesworth to the *Journal of Mental Sciences*, treat of a series of 3,445 patients admitted to Rainhill Asylum during a period of twelve years, 1,693 of the patients being males and 1,752 females. The patients were those concerning whose family history no details whatever were obtainable, and in whose direct parentage—fathers, mothers, and grandparents—or collaterals—brothers, sisters, uncles, and aunts—insanity, if it was met with, was regarded as an hereditary factor. Patients whose cousins only afforded evidence of insanity were not included in the class of hereditary insanity, as it was thought that there was an equal chance of such taint having been introduced by marriage from an entirely different family, and it could not be assumed without further proof that such taint belonged to the family of the patient. "Out of the whole series of 3,445 patients a definite hereditary taint of insanity, epilepsy, or a marked degree of eccentricity or peculiarity, either direct or collateral, was found in 965 cases, a percentage on the whole number of 28.01." Other authorities who have gathered statistics of a similar kind show that the percentage is generally larger than this.

Of these 965 patients, 419 were males and 546 females, thus exhibiting a percentage of 24.74 for male patients and 31.16 for females.

The writer of the article in the *Hospital*, commenting on these figures, says: "This striking difference has an interest which is enhanced by the fact that it harmonizes with the records of previous investigators, almost all of whom have found a higher percentage of hereditary taint among the female patients than among the male. The conclusion has hence been drawn that the female sex has a greater liability to suffer from hereditary insanity than the male. It has been suggested that the female sex has to pass during life through physiological crises—puberty, pregnancy, and the parturition, lactation, and the menopause—which constitute periods of danger, and which are prone to evoke into activity any latent hereditary taint of insanity; whereas in the male sex such danger is over when the age of sexual maturity is attained."

The Public Telephone as a Transmitter of Disease.

It has been asserted more than once that disease may be, and has been, conveyed by the agency of the public telephone. Dr. William Bissel of Buffalo contributed an article to the January number of the *Buffalo Medical Journal* in which he discusses the possibility of such a happening, and records some experiments he made with the view of testing its feasibility. He states that in order to discuss the question two important points must be considered: First, is the human body, and particularly the mouth, of well persons a possible carrier of infection? Second, if so, what part does the telephone play in transferring such infection? Dr. Bissel points out that it has been proved by laboratory investigations that microbes belonging to a particular species of pathogenic bacteria are, as

a rule, virulent, and that, further, such organisms, when carried in different locations, are capable of being shed, hence constituting a source of danger in the transmission of disease. It is well known that an individual to all intents and purposes in good health may be the carrier of noxious germs. For instance, the germ of croupous pneumonia is present in the mouth of every healthy person, and the diphtheria bacillus exists in the nose and throat of many persons who have never suffered from the disease. Again, those who have recovered from typhoid fever and cholera continue to throw off the germs of these respective diseases, while in cases of chronic pulmonary tuberculosis, when expectoration is profuse, the organism is expelled in large numbers. The experiments conducted by Dr. Bissel took place in the early part of this year, the telephones at three of the largest hotels in Buffalo being utilized for the purpose, and the particular organism for which search was being made being the diphtheria bacillus. After the most careful investigation it was found to be impossible to demonstrate the presence of the diphtheria bacillus on any of the telephones. It would thus appear as if there is little or no fear of contracting diphtheria by this means.

Yellow Fever and the Panama Canal.

A discussion took place at a recent meeting of the British Epidemiological Society, with regard to the risk of introducing yellow fever into Asia by the agency of the Panama Canal. A paper on the matter was read by Dr. Patrick Manson, who considered two points: (1) The risk of the extension of the fever to the populous regions of Asia involved in the opening of the Panama Canal; (2) the means to be adopted for lessening the risk. Dr. Manson drew attention to the fact that shiploads of laborers from China, Japan, and India would soon be plying between Panama and the seaports of Asia, and if the traffic were unrestricted the disease would inevitably be introduced into the populous, densely crowded, and insanitary cities of China and India. The author pointed out that the freedom from yellow fever hitherto enjoyed by Asia was like that of America, until recently, from cholera and the plague, due, not to any conditions unfavorable to its spread, but to the absence of direct communication with the localities where it was endemic. It was true that the parasite was present in the blood for a few days only at the commencement of the fever, but if taken from the patient during this period by a mosquito it retained its vitality in the body of the insect for eight or ten weeks, and might be at any time communicated by its bite to previously healthy individuals. The yellow-fever patient was in himself no more dangerous to others than was the sufferer from malaria, and it was the stegomyia that, like the anopheles, conveyed the germs from him to others, infecting them in turn. The cause of yellow fever having been shown to be owing solely to the presence of infected mosquitos, it was evident that it could not be carried by cargo or fomites, nor even by infected persons to places where stegomyia were absent. Quarantine and disinfection of cargo were alike useless, the sole means of prevention being the extermination of the stegomyiæ, for which, so far as shipping was concerned, sulphur fumigations of the hold and between decks were the most efficient, with the destruction of the larvæ in the bilges and water tanks.

Dr. Manson expressed his hope that the Americans, though they had no direct interests in Asia, would carry out the sanitary control of the canal with equal thoroughness, but it would be advisable that the civilized powers most concerned, such as England, France, Germany, Holland, Italy, Japan, and Siam should constitute an international board of supervision and subvention.

The measures he would recommend were simple enough, but must be inexorably enforced. Every vessel coming from, or having called at, a port within the yellow-fever zone should be boarded on entering the eastern end of the canal by an officer and assistants, whose duty it would be to destroy, by fumigation and other means, all stegomyiæ on board, and before leaving the canal it should be inspected by others who should satisfy themselves of the completeness of the work. To prevent the infection of a vessel in its passage through the canal, the country for half a mile on either side should be cleared of trees, standing water, and everything that could afford shelter for mosquitos or their larvæ.

In the discussion that followed, Dr. Strong of the United States Laboratory, Manila, Dr. Nuttall of Cambridge, Dr. Louis Sambon, and many others, took part, and it was the opinion of all, that the danger of carrying yellow fever to Asia during the construction and after the completion of the Panama Canal was a real and serious one, and that steps should be taken in good time to prevent, as far as possible, such a deplorable occurrence.

Bellevue and Allied Hospitals.

The last quarterly report of the trustees of these institutions has been issued recently. The improvements and changes which have been initiated are many, among which a better housing of the staff and employees is not the least. So far as the staff is concerned, the overcrowding still remains, for the simple reason that there is not room enough for the number of doctors required by the service. Furniture, however, has been bought, rugs placed upon the bare floors, and space provided for clothing, and the apartments occupied by the staff have been rendered in some degree fitting for the habitation of civilized gentlemen. The old Cornell Medical College is going to be converted into a dormitory for the women employees of the hospital, and many of the other dormitories have been painted and enlarged. Some of the employees have been given more wages, but the report states that further changes in organization and discipline are needed. The nursing service has been reorganized to some extent. Improvements and changes have been introduced in the Gouverneur, Harlem, and Fordham hospitals. The appropriations recently made by the Mayor of New York, for the purpose of building a new Bellevue and to reconstruct Fordham Hospital, lead to the confident expectation that it will not be long before this city possesses charity hospitals in keeping with her wealth and importance. Nevertheless, the Board of Trustees are to be congratulated upon the energy its members have displayed in remedying many of the abuses which have existed in Bellevue and the allied hospitals.

Local Treatment of Internal Diseases.

In the *Klinisch-therapeutische Wochenschrift* for February 15, 1903, Dr. Max Schüller emphasizes the importance to internal medicine of the recognition of the principle so dominant in surgery, of the application of remedies at the seat of the disease, using as a text the following case: A woman, aged thirty years, following severe influenza at the end of 1893, developed in March, 1894, pneumonia, which ran a very protracted course. In May violent stab-

bing pains, with dyspnœa of high grade, suddenly developed. On June 12 the greatly emaciated patient showed dulness on the right side behind up to the middle of the scapular region, with an absence of râles and vocal fremitus. A portion of the seventh rib was resected subperiosteally, and by incisions through the hepatized lung the abscess was drained, the periosteum sutured and the skin wound closed. Under an iodoform dressing healing took place by the first intention. Cultures of the sputum showed bacilli resembling Pfeiffer's influenza bacillus, and injection of them into the lungs of rabbits caused extensive fatal pneumonia. Tubercle bacilli were always absent. Convalescence was retarded; considerable fever, cough, with at times expectoration of considerable pus, and a dulness the width of two hands, remained. In August twenty punctures were made at various points in the dull area by way of probing for an encapsulated, purulent pleuritic focus, but without result. Then several injections of sterile salt-solution were made into the hepatized lung at several points—120 to 130 gms. in all being injected. After some days an alteration took place in the local and general symptoms; the expectoration became looser, the cough lessened, the dulness began to recede, the febrile symptoms became less marked, and the breathing improved. Steadily the respiratory sounds returned, the dulness lessened progressively, and by the end of October, it had disappeared and, except for slight catarrhal symptoms, nothing abnormal could be detected. The nutrition had increased notably and the patient had regained her fresh color and resumed her housework. In August, 1895, physical examination was entirely negative and the resected portion of the rib filled out by new bone. In this case the final restoration appears to have been brought about by the injection of salt-solution, previous medication, and also inhalations, having been without appreciable result. Certainly one could hardly attribute a special chemical action to the salt-solution. It appeared to act by rendering the infiltrating mass more fluid and by facilitating its extrusion via the bronchi. If at first only a few alveoli became free, this would permit the re-entrance of air into them, which would mean access to and circulation of the blood in those parts, and the first breach would thus be effected in the solid mass of infiltration. Such infusions into the lung should, in the author's opinion, certainly be employed in cases of delayed resolution of pneumonic or other inflammatory infiltrations, and still more in cases of so-called caseous pneumonia; of course with the presupposition of aseptic precautions, under which the injections can be carried out without danger.

Injections of Brain Emulsion in Traumatic Tetanus.

Dr. Anton Krokiewicz gives in the *Klinisch-therapeutische Wochenschrift* (Vienna) for February 8, 1903, the statistics of all the cases of tetanus treated by the subcutaneous injection of brain emulsion up to the present time. From his analysis it appears that sixteen cases have been so treated, of which thirteen recovered and three died. The author believes that the showing would have been even more favorable if the injections had been used in the beginning of the disease. Included in the sixteen cases are four which were treated under the author's own eye, by the injection of an emulsion of rabbits' brains, of which three recovered and one died. In three of the cases the disease exhibited a very great intensity, and in all the cases previous treatment with pharmaceutical preparations had been entirely without result, so that the recoveries could be ascribed solely to the action of the brain emulsion. The number of the injections were as many as six, and the injections were made daily, or at intervals of several days, according to the severity of the disease. They were well borne, the temporary suppuration at the site of injection never acquiring any importance, the abscess healing rapidly after incision. The author concludes that, considering the not specially favorable results of serumtherapy, this method, which is easy of application, deserves a wider application.

The Dangers of Internal Antisepsis.

In a pamphlet, "Les Dangers de l'Antisepsie Interne," Dr. Albert Robin recalls a case he reported of a syphilitic who, at the end of an intensive mercurial treatment for thirty-six days, was seized with an infectious bronchopneumonia of such gravity that she died in four days of very severe complications, which were entirely uninfluenced by the most active treatment. This observation, which had the aspect of a laboratory experiment, demonstrated that the method of internal antisepsis, which consists in saturating the organism with the most powerful antiseptics in order to prevent a microbic infection, moderate the multiplication of microorganisms, or attenuate their virulence, is not applicable in therapeutics, however rational its application may appear. The case showed, moreover, that the presence of mercury in the organism, far from attenuating microbic activity, appeared to be a powerful aggravating cause of the bronchopneumonia. Robin also reports the case of a woman suffering from secondary syphilis who had been subjected to an intensive mercurial treatment for fifteen days, in which time she received in all 0.75 g. of mercury in several forms (benzoate by injection; the bichloride and the metal in pills), or an average of 0.05 g. per day. During treatment she contracted typhoid fever, which assumed a grave form. Neither cold baths nor medication produced any appreciable effect; on the nineteenth day gangrenous spots and phlegmasia alba deolens appeared, and death occurred on the twenty-first day. In this case, then, mercurial saturation did not operate to prevent infection by the bacillus of Eberth, and did not lessen its virulence. Calomel, in particular, can be exceptionally and occasionally used to advantage as a purgative, cholagogue, or diuretic, when indications are present for it, but mercurial preparations, of whatever description, cannot serve as a basis for a systematic treatment, since alongside of a nullity of their antiseptic effects upon the organism, they possess the great inconvenience of retarding organic oxidation, whereas in the treatment of typhoid fever we are endeavoring to exalt the oxydizing powers of the organism, which are among the best means of defence that it possesses against intoxications. Outside of the restricted and altogether transitory indications which have just been outlined, mercurial preparations can then be of no value in typhoid fever. There is even reason for thinking that they are injurious, since in the author's case mercurial impregnation appeared to have been one of the causes of aggravation of the disease.

Roosevelt Hospital.—Dr. Victor Cox Pedersen was recently appointed Anæsthetist to the Roosevelt Hospital, First Surgical Division, and also Assistant Anæsthetist to the New York Polyclinic Medical School and Hospital.

News of the Week.

A Bill to Prohibit the Careless Distribution of Medicines, Drugs, and Chemicals.—An amendment to the Penal Code has been introduced into the Assembly of New York State with the above object. The amendment is as follows: "Careless Distribution of Medicines, Drugs, and Chemicals.—Any person, firm, or corporation who distributes, or causes to be distributed, any free or trial samples of any medicine, drug, or chemical compound, by leaving the same exposed upon the ground, sidewalk, porch, doorway, letter-boxes, or in any other manner, that children may become possessed of the same, shall be guilty of a misdemeanor, punishable by a fine of $25 for each offense, but the section shall not apply to the direct delivery of any such article to an adult."

Dr. Roux Wins Osiris Prize.—The Institute of France has awarded the Osiris prize of 100,000 francs to Dr. Roux of the Pasteur Institute, the discoverer of the anti-diphtheria serum.

Manhattan State Hospital West, Wards Island.—Owing to the energy of Dr. E. C. Dent, the Superintendent of this institution, many improvements have recently been made and the service has become remarkably active. The operating room has been fitted up with all the modern improvements, and new instruments have been purchased. A weekly operative clinic in gynecology, comparing favorably with that at any of the large hospitals, is conducted by Dr. Leroy Broun. Modern appliances for hydrotherapeutic treatment have been installed. These have been modelled after the institution of Dr. Simon Baruch, the well-known authority on this subject, and an attendant has been specially trained under his direction to take charge of this department. The Nauheim Baths are also to be introduced. A special ward has been divided off for experiments with the Russell treatment for tuberculosis, which has been reported as successful at the Post-graduate School. Dr. John Russell has taken charge of these experiments in person, and, so far, the results secured have been especially encouraging. Numerous specialists have been recently appointed on the Consulting Board, and researches are being instituted by them, by the resident staff, and by prominent physicans of this and of other cities, as Dr. Ferd Valentine, T. M. Townsend, John Russell Kent, and others. The Board of Consulting Physicisians at present holds monthly meetings at the hospital, and many of its members make frequent visits each week to the institution. Dr. Austin Flint was recently elected President of the Medical Board, and Dr. Robert Coleman Kemp, secretary.

The hospital possesses excellent material and facilities for work, and it is the evident intention to develop an extremely active service.

College of Physicians of Philadelphia.—At a stated meeting, held April 1, Dr. Morris J. Lewis read "A Memoir of the Late Dr. Francis W. Lewis." Dr. Thomas R. Neilson presented "A Report of a Case of Suturing of the Omentum to the Abdominal Wall (Talma) for Cirrhosis of the Liver Twenty-one Months after the Operation." The patient was much improved, and there was no further recurrence of the ascites, although the liver remained enlarged. Drs. Henry M. Fisher and W. W. Keen presented "A Report of a Case of Suturing of the Omentum to the Abdominal Wall (Talma) for Cirrhosis of the Liver Twenty-five Months after the Operation." Ascites recurred several times after the operation and required paracentesis, but there has been no further return in twenty-one months, although the spleen, previously large, as increased considerably in size. Dr. Chas. H. Frazier demonstrated a patient in whom he had performed a similar operation for a like cause thirty-five months ago with relief of the ascites and other symptoms. The liver is reduced in size, while the spleen is enlarged. Drs. P. Savary Pearce and L. Napoleon Boston presented a communication entitled "The Blood in Epilepsy; Experiments on Animals," in the course of which they detailed the results of studies of the blood from cases of essential epilepsy, with relation to the hæmoglobin-percentage, the number of red and of white corpuscles, with the differential enumeration of the latter, and also the results, as manifested especially in changes in the blood, induced by inoculation of rabbits with the blood from such patients.

The Denver Academy of Medicine has been organized to maintain a home and meeting place for the profession, and to provide for a medical library. The officers chosen for the ensuing year are: *President*, Henry Sewall; *Vice-President*, George B. Packard; *Trustees*, W. A. Jayne, W. W. Grant, Thomas H. Hawkins, L. E. Lemen, H. W. McLauthlin, I. B. Perkins; *Secretary*, C. K. Fleming; *Treasurer*, Frank E. Waxham; *Librarian*, C. D. Spivak.

Mosquitos on Vessels.—Assistant-Surgeon Grubbs, who is in charge of the Gulf Quarantine Station, has been investigating the question as to whether mosquitos infected with yellow fever can carry the disease to any extent, and if so, under what conditions. Dr. Grubbs inspected eighty-two vessels arriving from ports where the yellow fever-bearing mosquitos are prevalent, and of these vessels, sixty-five had no mosquitos on board at any time during the voyage; five had the insects on board at port of departure; nine reported the appearance en route of harmless mosquitos, and three conveyed stegomyia to the station. The three last ships were from Vera Cruz, a yellow-fever port, and the voyages lasted on an average, seventeen days. Dr. Grubb came to the following conclusions: First, that mosquitos can come aboard a vessel under favorable conditions when the vessel is not more than fifteen miles from shore; second, that stegomyia can be carried from Mexican or West Indian ports to those of our Gulf States; third, that they can board a vessel lying at anchor a half mile or less from shore, being conveyed by the open lighters used or flying aboard; and, finally, that a vessel moored a short distance from land may become infected with yellow fever.

Red Cross Affairs.—It is likely that the International Red Cross Society, at its meeting in Geneva next summer, will be called upon to settle some of the points in the dispute pending among the members of the American National Red Cross Society. It is stated that a report of the present dissensions in the American Society will be made to the Geneva Conference by Brig.-Gen. John M. Wilson, former Secretary John W. Foster, and others, comprising the committee of Washington members of the society. A memorial is to be prepared for the International Conference pointing out the illegality of the present American organization through the violations of its charter and the withdrawal of the President of the United States and his Cabinet from membership on the general board.

Sanatorium for New Jersey Consumptives.—Plans have been prepared for the erection of the New Jersey Tuberculosis Home at Lebanon. Dr. Charles Kipp of Newark is president of the board of directors, Dr. James Green of Elizabeth is secretary, and Col. A. Stevens is treasurer. The

building is planned to accommodate about 250 patients. Six physicians will reside in the grounds, and the superintendent will probably be a bacteriologist. Indigents only will be admitted as patients, and those in an advanced stage of the disease and deemed incurable will not be accepted.

The New Jersey Legislature has appropriated $50,000 for the purchase of the land, and a sum of $300,000 will be appropriated when those in charge of the proposed institution are in a position to build.

More Deaths from Typhoid Fever in Ithaca.—Two persons died of typhoid fever in Ithaca on April 4, making a total of five deaths from the disease during the week.

Fordam Hospital Plans.—The architects have been chosen to draw the plans for the new City Hospital to be erected at Fordham and for which $500,000 has been appropriated. The trustees have not yet made a selection of land for the site, but the building will probably be erected south of Pelham avenue and west of the Bronx river. It is to be four stories in height and built to accommodate 150 patients. Plans are also being prepared for an additional wing, to cost $125,000, to Gouverneur Hospital for the accommodation of sixty patients.

Political Control of the State Institutions.—Under Governor Odell's centralization scheme for the various State hospitals, charitable reformatory institutions and prisons, the expenditure of about $2,500,000 granted for supplies will be in the hands of politicians, who will be able to expend the money as they choose, with practically no let or hindrance. This is the direct outcome of the Governor's action in ousting the prominent men and women of the Charity organization who used to exercise a wise supervision over the State hospitals for the insane. The MEDICAL RECORD has consistently taken the course of strongly condemning the arbitrary action of the Governor, which would seem unpleasantly to resemble the policy of another noted political leader, "unto the victor belong the spoils."

The Late Prof. T. Gaillard Thomas.—At a meeting of a committee appointed by the Medical Board of the New York Infant Asylum, held on March 30, 1903, the following resolutions were adopted:

Whereas, The late Dr. T. Gaillard Thomas, for several years and at the time of his death, was Consulting Obstetrician of the New York Infant Asylum and President of the Medical Board, an office in which he exhibited wise counsel and charming geniality, and

Whereas Dr. Thomas was a man of great eminence, well known to the medical profession throughout the world, by virtue of whose character and renown much honor was reflected upon this institution, therefore

Be it resolved, That the Medical Board of the New York Infant Asylum record the death of Dr. Thomas with a sense of deepest regret and inexpressible loss; and further

Be it resolved, That a copy of these minutes be sent to the bereaved family, and to the principal medical journals, and inscribed in the records of the New York Infant Asylum.

(Signed)

J. MILTON MABBOTT, M.D.,
GEORGE TUCKER HARRISON, M.D., } Committee.

In Honor of Dr. Thomas L. Maddin of Nashville.—The annual meeting of the Nashville Academy of Medicine and the Davidson County Medical Society was held on April 7 at Tulane Hotel, Nashville, Tenn., when a banquet was given in honor of Thomas L. Maddin, M.D., of Nashville, Tenn., he having completed fifty consecutive years of membership in the Tennessee State Medical Society.

Navy in Need of Young Surgeons.—There is a great demand in the navy for young medical officers. The need of assistant surgeons in the medical corps is very great, there being at the present time twenty-seven vacancies in that grade. Surgeon-General Rixey is trying to attract young medical men into the service. He is now in the South inspecting a hospital at Pensacola. He intends addressing several medical colleges and calling to the attention of the students the desirability of a naval career. Not long ago he delivered an address at the Jefferson Medical College, in which he dwelt upon the opportunities for young medical graduates in the navy. The work to be performed by the medical corps in the navy is growing every year. The authorized strength of the navy now is about 38,000, and within the next six years will probably reach 50,000. The enlistments and reënlistments require the constant attendance of surgeons to make physical examinations and besides this routine work there are fourteen naval hospitals with naval stations, navy yards, and receiving ships, where the services of members of the naval corps are needed. Applicants for admission in this branch of the service must be between twenty-one and thirty years of age, physically sound, of good high-school education, and master of their profession to a degree that would insure a successful career in civil life.—*Philadelphia Press.*

Instruction in Tropical Diseases in Paris.—The appointments to the Institute of Colonial Medicine in Paris have now been completed. Professor Brouardel, director; Professor Debone, dean of the school; Professor Chantemesse, teacher of bacteriological and hematological technique; Professor Blanchard, parisitology; Professor Le Dentu, tropical surgery; Professor de Lapersonne, tropical ophthalmology; Professor Wurtz, tropical hygiene; Professor Jean Selme, tropical skin diseases.—*Journal of Tropical Medicine.*

Plague in India.—The plague epidemic throughout India goes on steadily increasing. The deaths in the week numbered 25,882, as against 25,870 for the previous seven days, and 12,695 for the corresponding week last year. Bombay city returned 716 deaths; Calcutta, 171; Karachi, 25; and Poona about 600. The Bombay Presidency reported 10,835 deaths; the Madras Presidency, 604; Bengal Presidency, 2,941; the United Provinces, 2,995; the Punjab, 3,581; the Central Provinces, 1,203; the Mysore State, 526; the Hyderabad State, 1,640; Central India, 435; and Kashmir, 1,717. The increase is general, but Poona and some other places seem to suffer out of all proportion to the number of the population. During the past fortnight the death rate in Poona has been about 500 per 1,000 per annum. In Calcutta the rate has never reached 100, while even in Bombay it has not exceeded 150 in any of the outbreaks.—*The Lancet.*

Triple Vaccination in France.—The French Government has just promulgated a new code of sanitary regulations. This code among other regulations contains the proviso that for the future three vaccinations instead of one, as hitherto shall be obligatory upon all French citizens. The first is to be made during the first year of infancy, the second in the eleventh year, and the third in the twenty-first.

An Anti-vivisection Bill in Great Britain seeks to amend the statute which already regulates and controls the performance of experiments upon live

animals. Its main object appears to be the abolition of the existing provisions for the performance of of certain experiments under certificates, which without certificates are not permissible Those especially aimed at are, no doubt, those in which it may be desired to dispense with the administration of an anæsthetic. There is also in the bill a section ordering that "there shall be present throughout the whole course of the experiment an inspector," and no such experiment shall at any time be performed or continued save in the presence of such inspector aforesaid." Power is given to the Secretary of State to appoint a sufficient number of inspectors for this purpose. Their duties, however, would be obviously such as only highly qualified members of the medical profession could adequately perform, and the questions to be decided by them are now safely left in the hands of the highly qualified members of the medical profession, whose experiments, at times, under the existing act, lawfully include those upon live animals. These experiments are already subject to conditions with regard to inspection and other matters, the stringency of which, it is proposed, should be increased in other directions besides those to which we have called attention. Members of Parliament who have considered the existing act and are acquainted with the statistics relating to its subject matter will, for the most part, be satisfied that the protection which it affords to dumb animals is sufficient without the additional restrictions proposed in the bill just brought forward. —*The Lancet.*

Pension Fund for Nurses in England.—At the annual meeting of the Royal National Pension Fund for Nurses, recently held under the chairmanship of Sir Henry Burdett, K.C.B., solid progress in all departments was reported. In the pension branch 869 policies had been issued as against 842 in 1901, an increase all the more satisfactory from the consideration that 1901 was the record year of the fund. The amount distributed in sick pay during the year was £1,568 ($7,840), and the total funds increased from £648,725 ($3,243,625) to £734,182 ($3,670,910). —*British Medical Journal.*

Dangerous Essences.—Owing to the ill-health of the reporter M. Laborde, M. Jouffroy, in the name of the Commission on Alcoholism, closed the discussion on "Dangerous Essences" before the Académie de Médecine of Paris by moving the following conclusions, which were unanimously adopted: (1) The Académie declares that all essences, natural or artificial, without exception, as well as extractives incorporated with spirits or with wine, constitute dangerous and harmful drinks. (2) The Académie declares that the danger of these drinks resulting at once from the essences and from the alcohol which they contain, they deserve proscription, whatever may be their basis, and at any rate there is need to increase the tax in such away that the excess tax becomes in a measure prohibitive. (3) The Académie particularly calls attention to the danger of apértifs—that is, drinks containing essences, and alcohol, which are taken fasting. The fact that these drinks are taken before meals renders their absorption more rapid, and their toxicity more active.—*British Medical Journal.*

Obituary Notes.—Dr. Reinhard H. Weber died in Philadelphia on March 29 at the age of fifty-nine years from cerebral hemorrhage. He was born in Hesse-Darmstadt and came of a distinguished family of German physicians, his father having been in the service of the German Government. He was graduated from Jefferson Medical College in 1865.

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent.)

PARLIAMENTARY—HOSPITAL DISTRIBUTION—ANTI-TYPHOID—MULTIPLE MYELOMA—THE APPENDIX—SANATORIA—NOTIFICATION ORDER—SIR M. FOSTER—DR. HUTCHINSON, M.P.

London, March 20, 1903.

From the reply to a question in the House of Commons it appears that Trinity College, Dublin, recently applied for authority by a King's letter to confer degrees on women. Some technical difficulties have to be overcome as to the construction of the college statutes, but it is expected that authority will shortly be given.

The expected bill dealing with the certification of deaths, is not to be introduced this session, notwithstanding the recommendation of the recent committee, and the earlier one of 1893.

Bills have also been introduced dealing with reciprocal arrangements with Canada respecting the Medical Acts. The second reading of these is on the program for to-day, but is not likely to be reached.

The distribution of our hospitals is exciting more attention outside as well as inside the profession. Of course it is a public question, and a difficult one. Many newspaper correspondents have, therefore, something to say about it, though these suggestions do not of en proceed from full or accurate information. Now that it is decided for Bartholomew's to keep its old position, the means of extending its work is being considered. I mentioned to you before that there are several buildings on the premises which might just as well be elsewhere. The chaplain's house and the treasurer's house, as well as the chapel, need not be on the premises, and the nurses' home could very well be removed. Those who advocate the removal of some of the hospitals to the suburbs have been urging that St. George's and King's College should both seek new habitations. In regard to the former there is something to be said on both sides. The latter is a case of need.

The Council of the King's Fund is in favor of removals where practicable, and it is whispered that they are also urging some of the smaller, and especially special, hospitals to amalgamate. No doubt such a plan would be an advantage if it could be carried out, but there are difficulties even with these. One of the most obvious is that many of them are rival institutions, and, supposing amalgamation to be effected, there is nothing to prevent another rival being established.

We seem to be on the eve of attaining an effective antitoxin for typhoid fever. A paper at the Royal Society by Dr. A. Macfadyen gives an account of investigations he has made conjointly with Dr. Dewar with bacteria exposed to intense cold by means of liquid air. They are not killed by such exposure for long periods, but frozen into brittle masses, which can then be triturated. The temperature inhibits chemical change, and the cell plasma can be separated. This has been used to render animals immune, and their serum is both antitoxic and bactericidal. Animals inoculated with a lethal dose of living bacteria have recovered under the influence of this serum, which it would seem is both preventive and curative.

Multiple myeloma is a convenient term enough for certain rare cases in which myelogenic new growth has been found, but in which there are such differences that two if not more types may be distinguished. Dr. Parkes Weber related a case at the Medico-chirurgical Society which he thought was probably the second diagnosed *during life* in England, the first being Dr. Bradshaw's in 1898. Dr Weber's case was complicated with syphilitic gummata, chronic rheumatoid symptoms, and ulceration of the duodenum. Early in 1900 the urine was found to contain the Bence-Jones' proteid, and Dr. Rob. Hutchinson estimated the amount excreted as 15 grams per day. Later anæmia and cachexia were marked, and by January, 1901, the blood examined gave only 23 per cent. of the normal hæmoglobin. No atypical cells were found among the leucocytes. A year later the man died from intestinal hemorrhage, which the post-mortem showed to be derived from ulceration of the duodenum. The Bence-Jones albumosuria had persisted to the last. The marrow of all the bones examined at the autopsy was affected by a diffuse sarcoma-like growth of rounded or polyhedral mononuclear cells. Professor R. Muir examined the growth microscopically. It was confined to the bones, and formed no projecting tumors from them, and no other parts of the body were affected. Chemical investigation by Dr. R Hutchinson and Dr. J. J. R. Macleod failed to find in any of the organs or tissues a body giving the same reactions as those of the Bence-Jones' proteid in the urine, Nor could they obtain it from normal red bone marrow.

They did obtain, however, a similar but not identical proteid from the vertebræ and ends of the femur, but it differed in the temperature at which it coagulated, and in not being redissolved on boiling. They think the marrow must have been the seat of production of the proteid rather than any unassimilated digestive proteid, as suggested by some. Dr. Weber gave the following as the conclusions he had formed: (1) Bence-Jones' albumosuria is always the result of disease of the bone marrow. (2) It is due to an abnormal metabolic or degenerative process in the myelocytes or in the tumor cells derived from them. (3) The reason why it is generally associated with myelogenic tumor formation is that the tumor cells derived from bone-marrow cells, however closely they may resemble true marrow cells, are more prone to abnormality than real myelocytes. (4) Non-myelogenic tumor cells are not affected in the same way and therefore metastatic tumors in the bone-marrow do not give rise to Bence-Jones' albumosuria-like myelogenic tumors.

Dr. T. R. Bradshaw said that when five years ago he brought a case before the society not more than six had been described, a number which has now increased to thirty-two. He thought myelopathic albumosuria should now be regarded as a definite disease. The proteid appeared to be intermediate between an albumin and an albumose. The latter name was applied to bodies which differ a good deal in chemical reactions. The idea of an albumose is a proteid derived from albumin, but of less molecular weight and of less complexity. The Bence-Jones' albumose has not been found, except in association with bone tumors, and the change in the urine is marked before any symptoms of bone disease occur. The new growth in the bones seems to be the seat of the formation. Dr. R. Hutchinson agreed with this, though it seemed to him difficult to see how the destruction of these cells could give rise to the great quantity of proteid passed in the urine. Dr. Macleod thought the proteid was rather an albumin. Its biuret reaction was always violet—not red.

The appendix vermiformis continues to claim attention from various points of view. At the Medical Society, on the 9th inst., Mr. Frederic Eve of the London Hospital discussed the conditions which simulate inflammation of the tube and cases of abscess in unusual positions. He related five cases of tuberculosis of the cæcum, all having a history of recurrent attacks of pain, sometimes coming on suddenly. One was, for years, supposed to have a gastric ulcer. The pain being referred to the epigastric region. In nearly all cases there was constipation, but vomiting in only one. The appendix was only found involved once and was not tuberculous. The difficulties in diagnosis between affections of the appendix, gall-bladder, kidney and intestines, in some cases, were dealt with. The localization of pain and the position of an abscess varied greatly. In one case the pain was referred to the right loin, the tip of the appendix being adherent beneath the liver. In another the complaint was of pain in the *left* flank. Pelvic inflammations must not be forgotten.

Mr. Gould (president) mentioned cases of tuberculous disease in the neighborhood of the appendix which led to errors of diagnosis. In one, recovery occurred after an exploratory laparotomy. Other cases were twisted pedicle, duodenal ulcer, perforating. On the other hand, appendicitis had been mistaken for ovarian tumor, and concretions had been found free in the peritoneal cavity without any fluid.

Dr. De H. Hall mentioned a case of a woman who had a lump in the position of a femoral hernia, and found to be the appendix passed down the sheath. Dr. Caley said that when pain had been long continued colitis should be suspected, and cited such a case in which the appendix was removed without benefit. Another difficult case proved to be a perforated ulcer of the cæcum.

In connection with the foregoing let me add a few points from the recent Hunterian lectures of Mr. McAdam Eccles, at the Royal College of Surgeons. First he said the appendix is an intraperitoneal organ, always suspended by a fold of peritoneum, but with its extreme tip usually free. It cannot, therefore, be reached without incising the parietal layer of peritoneum. Another fact is the direct communication with the cæcum proper. This is a safety-valve, and not in the vast majority of cases the entrance by which a foreign body passes into the tube. The lumen is smaller than many of the bodies which have been said to have passed through it. The *position* of the appendix within the abdomen is important, but the lecturer said it was almost impossible to guess where the tip was in a given case, without exposing it, and he cited instances of unusual positions, and said there are three, which may be conveniently termed normal: (1) pointing upward and inward toward the spleen; (2) downward and inward over the brim of the true pelvis; (3) directly upward behind the cæcum. In more than half of nearly 200 cases he had found it in the last. As to appearances, Mr. Eccles described those which might decide that the organ was healthy enough not to be excised, though he admitted that it would be impossible to say it was absolutely normal without microscopic examination. As to its physiology he took a middle course, considering it as partly absorptive and partly excretive. Pathologically, inflammation is the chief feature, and the lecturer stated his belief that every case is due to bacteria.

The Earl of Derby, presiding at a recent meeting of the Association for the Prevention of Consumption, remarks that the Berlin conference had considered the reason why treatment successful in one place was not in another. In Prussia deaths from consumption had fallen from 31 to 21 per 10,000, in England from 24 to 19. He thought there was a more wide-spread knowledge of the subject in Germany, and more general resort to sanatoria, also greater willingness to submit to regulations. He believed workmen would, through their friendly societies, establish for themselves such institutions as were necessary. In England fifty-two sanitoria had been erected during the last four years. He suggested that beds in the vacant smallpox hospitals might be utilized for consumption. I suppose he meant that they could be so used between epidemics. The association passed a resolution in favor of a law forbidding spitting in public places.

The London County Council has just sent a circular to the practitioners in its district to inform them that they have put in force the notification act in reference to measles.

Sir Michael Foster announces his intention to resign his Cambridge professorship before the next term. Looking at his vacillation about his seat in Parliament, one feels doubtful whether he may not again change his mind.

We have a new doctor in Parliament. The bye-election at Rye resulted in the return of Dr. C. F. Hutchinson, M.D., Edin., 1874, who several years ago retired from practice.

OUR LETTER FROM THE PHILIPPINES.

(From Our Special Correspondent.)

ANTISERUM FOR RINDERPEST—PHARMACY IN THE PHILIPPINES—INJURY TO DRUGS BY CLIMATE AND INSECTS—STATUS OF SURGERY—AN OPENING FOR DENTISTS—FORTUNE IN DAIRY FARMING.

MANILA, P. I., February 20, 1903.

THE recent epidemic of rinderpest having destroyed so many cattle and carabao as to interfere seriously with the cultivation of crops, the commission is about to import a large number for sale at cost to the Filipino farmers. As rinderpest still prevails in the districts to which they are to be sent, the government is immunizing the newly purchased animals against the disease by the use of Dr. Strong's antirinderpest serum, which confers an immunity lasting six or seven years. The mortality following inoculation is small—less than 2 per cent. About 20,000 carabao, now collected at Amoy, China, are undergoing inoculation prior to shipment to the Philippines. Inoculation of animals against rinderpest is done gratuitously for private owners at the government laboratories in Manila. This fact has been widely advertised through the provinces, but with little effect, as the Filipino is slow to accept new ideas, and would rather take his chance of losing his animals than submit it to a procedure which he does not understand.

The commission is at present considering the question of raising the educational standard for persons desiring to practise pharmacy. As the matter stands, licensed pharmacists are required to study two years longer than assistant pharmacists. As compared with those of pharmacists in the United States, the qualifications required are not high—but it should be remembered that neither the intellectual nor the general educational standards of the Filipino are anywhere near as high as in the United States, and that the education and civilization of the natives are both superficial and imperfect.

The character and quality of many drugs, medicines, and articles of medical supply are affected very unfavorably by the Philippine climate, as the army medical authorities especially have found out. Heat, moisture, intense light, rust, molds, and insects all play their part in the work of destruction. Ammonium carbonate, chloral, and similar drugs liquify. Some fluid extracts, as that of wild cherry, deposit heavy precipitates; the gelatin coating of pills becomes leathery and insoluble; sodium salicylate turns purplish. Volatile substances require glass-stoppered bottles, as there is great loss of substance and virtue through ordinary corks; original tins of Squibb's ether, stored for some little time, are found to be empty, or nearly so, the ether having volatilized

through the metal of the tin. Flaxseed, farina, oatmeal, and similar articles soon swarm with weevils in spite of being put up in metal containers—a few eggs of the weevil present when the article was originally packed developing rapidly into a horde of worms and insects. Quick-lime rapidly a r-slacks and chlorinated lime loses its chlorine through the bottle-stopper, both becoming worthless for disinfection purposes. Oil silk loses its oil, and sections stick together so tightly as not to be detached without tearing; bandages, bedding, and fabrics generally are liable to undergo dry rot, be cut through by mold or riddled by white ants or moths. Leather is rapidly spoiled by mold, becomes brittle and ultimately crumbles to powder; leather is a'so a favorite food of white ants and the large Philippine cockroaches. In the rainy season all leather must be sunned frequently. Articles of rubber lose their elasticity so rapidly on exposure to air that in the army only a six month's supply is now issued at a time. Tins are cut through by rust and the contents spoiled by the action of air, bacteria or insects. Instruments must be watched most carefully to prevent their being promptly ruined by rust; those required for daily use are commonly kept in glycerin or carbolized oil, while instruments in their cases must be wrapped separately in pieces of paraffined paper. Wooden boxes undergo dry rot and frequently become so honeycombed by white ants, if allowed to stand in one place any length of time, as to collapse at the first attempt at handling. For all these reasons the lot of the pharmacist in the Philippines is not an especially happy one. One rift in the clouds for him consists in the fact that the native will accept anything in the way of medicine, particularly if it have pronounced color, a bad taste, and a well-marked cathartic or emetic action. Counter prescribing is a large feature of the retail drug and medicine trade in the Philippines, as might be expected in a country the lower classes of which are so ignorant and impoverished, and in which there are so few physicians. During the cholera outbreak the drug stores did a rushing business in specifics for cholera at a peso or so a bottle. If one proved valu less, the native did not lose faith thereby in the potency of drugs, but tried the "sure cure" advertised by the rival pharmacist. In the provinces the retail drug trade is held by Spaniards, or Spanish half-castes; the wholesale drug business is controlled by Germans. There is much substitution and adulteration of drugs, and the establishment of a few well-equipped American drug stores supplied with the best products of American wholesale manufacturing pharmacists would prove a paying investment. Many of the American and English physicians in practice in Manila prefer to import their own medicines so as to be certain that the patient receives the special drug, of the proper strength prescribed. The articles kept in Manila drug stores are not well selected, according to our way of thinking, nor is this selection very large. Patent medicines and secret preparations are very popular with the natives, and these form a large part of the stock in trade. To send to the United States or Germany for an article not on hand means a delay of three or four months, though occasionally a desired article can be procured in Hongkong. This difficulty in procuring at any time the supplies wanted is a no small hindrance to the most satisfactory medical practice. The supply of surgical instruments is even more limited, and some first-class American instrument maker would do well to establish a well-equipped agency here.

The amount of surgery to be done is relatively small in the Philippines, from the absence of the railroads and factories which furnish the greater part of surgical cases in more civilized countries and because the native has an instinctive dread of any operation requiring cutting, which, in the hands of the Spanish and Filipino doctors, usually turns out badly in the rare cases in which they are undertaken. As yet, the natives have not been educated up to the possibilities of modern aseptic surgery. The obstetrician has little field for practice among the natives, as child-birth is largely left to midwives, who rely on expression and kneading of the uterus to bring about delivery. Native women are very modest about exposing the genitalia to male physicians, and for this reason little opportunity for practice is afforded the obstetrician and gynecologist. Specialists in diseases of the eye, ear, nose, and throat generally do well after acquiring the confidence of the natives, as also the practitioner of internal medicine. American dentists in the islands are doing well and are preferred by the natives to the Spanish or Filipino dentists. The Filipino is very proud of his personal appearance, and will pay any price for gold fillings or prosthetic dentistry. Of the two, dentistry is much more remunerative than the practice of medicine and surgery among the natives. As the Philippine climate seems to have a very unfavorable influence upon the teeth of Americans, causing them to disintegrate rapidly, the dental work required among the white population is much larger than among the same class and numbers in the United States. At present the supply of dentists is not equal to the demand.

A small fortune also awaits one who will establish a dairy farm near Manila and provide a supply of milk of good quality and undoubted purity. The dairy should be modeled on the lines of the Walker-Gordon laboratories of the eastern cities of the United States, so that a supply of proper food for nursing infants might always be available. But little fresh milk is now obtainable in Manila, and this is so certain to be contaminated by the filthy methods of the natives as to be unfit for use without boiling. Native cattle are few and far between, and have for centuries been raised for draft rather than milk purposes. Carabao and mare's milk are obtained with difficulty, and the former is not relished by many persons The supply of goats' milk is very small, and this is so rich in fats as to cause indigestion in infants in this climate. Better than milk from the above animals is the unsweetened canned condensed cream, properly diluted, but this soon becomes distasteful to most adults, and cannot be used for children for any great length of time, except to supplement a supply of fresh milk, without marked impairment of the health and condition. A thick creamy milk is brought up from Australia on refrigerator ships, and is fairly palatable, as a change, when diluted with hot water. It is, however, undoubtedly preserved by the addition of boric acid or formaldehyde, and frequently becomes "stringy" and bad tasting. Malted milk is much used, but has its limitations. As a result, the nutrition of that class of patients, who, in the United States, would be placed on a milk diet, suffers; while the nourishment of infants whose mothers have an insufficient flow of breast milk is always a serious matter, as it is difficult to secure wet nurses from among the native women. The establishment of a dairy run under modern methods would thus be hailed as a boon by housekeepers, and as an important adjuvant in the treatment of the sick and feeding of infants by physicians, nurses, and mothers in these islands.

NEW LAMPS FOR PHOTOTHERAPY.

To the Editor of the Medical Record:

Sir: I note in your issue of March 28 a communication from Dr. Cleaves, in which she says: "From the beginning of my use of the ultra-violet light disassociated from the luminous and heat rays," etc.

If Dr. Cleaves has devised a lamp or other apparatus whereby she has disassociated the ultra-violet from the luminous rays so as to enable her to use the ultra-violet alone, it would be interesting to know the exact devices employed by her. It certainly cannot be accomplished by any of the lamps referred to in her article. It, of course, can be accomplished with the aid of a quartz prism or a diffraction grating, but the lamp with these attachments would not be as useful therapeutically as if these attachments were omitted.

In another part of the article it is stated: "Bang, in his experiments with an ordinary arc consuming 1,375 volts per hour, found," etc. This sentence, I think, would puzzle the most expert electrician unless he referred to Bang's original article (*Deutsche medicinische Wochenschrift*, September 26, 1901), where he would learn that Bang operated the lamps referred to under a pressure of fifty-five volts with a current strength of twenty-five amperes—in other words, the electric energy in constant use during the time of the experiment amounted to 1,375 watts (not volts). The lamp made by the Kny-Scheerer Co. has but little resemblance to the Bang lamp. In reality it is a copy of a lamp introduced by the Sanitas electricitats Gesellschaft of Berlin, and described by Dr. Kattenbracker in *Treatment*, February, 1902. An equally convenient lamp with probably double its efficiency on same expenditure for current has been introduced by Reiniger, Gebbert and Schall of Erlangen. Another twin-arc lamp offered by Heller, Coudray et Cie, Paris, appeals to me still more strongly. A twin arc lamp with metal-cored carbons is offered by Isenthal & Co. of London. These lamps are all of the low-tension arc type, working under a pressure of about fifty-five volts and with a current of eight or ten amperes, and are richly endowed with luminous rays with a good output of ultra-violet. The condenser-spark lamps, however, are comparatively feeble in luminous rays, but exceedingly rich in ultra-violet.

Since the publication of my recent paper in your issue of March 7, I have been asked by several as to whether the low-tension arc or the high-tension condenser-spark lamp is to be preferred. This will depend upon the case one purposes to treat. If the lesions are strictly superficial the condenser-spark will prove the more satisfactory, but if the lesions involve the entire thickness of the derma or exist beneath it, the low-tension lamp will be found the more efficient.

New York Medical Journal, April 4, 1903.

Syphilitic Pseudotabes.—J. Collins reports a case of this nature and discusses the differential diagnosis of tabes. Conditions calling for differentiation from tabes are multiple neuritis, flat feet, paresis, and multiple sclerosis. The latter, Collins considers to be the disease which, in an atypical form, is most readily mistaken for tabes. When the sclerotic patch or patches occur in the posterior columns, the symptoms that result are those of tabes, and so long as the sclerotic areas are confined to those columns, the clinical picture continues to be that of tabes. It is only when they develop in other parts of the cord, and produce characteristic symptoms, such as tremor, nystagmus, speech disturbance, and possible increase of the tendon jerks in the upper and cephalic extremity (knee-jerks and ankle-jerks being lost on account of the lesion of the posterior columns), that the disease can be differentiated Even then it requires repeated observation and considerable study.

Terminal Coma in Diabetes.—A. R. Elliott gives the histories of four fatal cases. Concerning the treatment of coma from this cause, he observes, that prophylaxis is of the greatest importance. The earliest indication of the trend of events is the appearance in the urine of the acid toxins. The first of these to appear is usually acetone, which is readily detected by the sweet chloroformic odor it imparts to the breath and urine of the patient. Subsequently, diacetic acid and β oxybutyric acids make their appearance and occasion the beautiful burgundy red coloration which follows the addition of a solution of perchloride of iron to the urine, and which is known as Gerhardt's reaction. Diet should be relaxed. The patient should be protected against nervous disturbances, cold, and fatigue. All sedatives and narcotics should be discontinued and elimination favored in every possible way When the prodromes of coma appear, the patient must be immediately put to bed, a stimulant given, and if the heart is weak, a good-sized dose of digitalin had better be administered subcutaneously. If the bowels have not been previously well evacuated, a laxative is given and a high soap suds enema for cleansing purposes. Alkalies which are the physiological antidotes of the acid toxins, should be at once begun in enormous doses, as much as it is possible to get the patient to take, and normal salt-solution charged with sodium bicarbonate may be used freely by bowel and subcutaneously. Inhalations of oxygen should be freely used.

Journal of the American Medical Association, Apr. 4, 1903.

Primary Endothelioma of the Gall-bladder.—W. Becker reports a case occurring in a woman of sixty-five years, and gives full autopsy findings with several illustrations. He says that endothelioma, hemangio-endothelioma, and perithelioma may be blastogenetically alike, but the first tumor differs materially from the last two in the mode of growth, histology, and clinical aspect. One need but think of the functional difference of the normal elements to appreciate this fact. Endotheliomata are only relatively malignant. A great number of tumors reported under this name are essentially inflammatory.

The Bacteriology of Cystitis.—R. C. Longfellow says that in cystitic urine, as a rule, both cocci and bacilli are present; either one may exist in excess of the other, both exist equally or only one form of bacteria be present. Among the cocci present are the staphylococcus pyogenes aureus, albus or citreous, the micrococcus ureæ, sarcina urinæ, the urobacillus liquefaciens septicus, the streptococcus pyogenes, the zoogloea masses, and the gonococcus. The bacilli are usually the coli communis, the tubercle, and in cystitis, during the middle or latter end of a typhoid attack, the Eberth bacillus. Thiogenic bacteria may be present, whose peculiar function is to convert sulphuretted hydrogen into more potent compounds of sulphur, and play no small rôle in cystitis. The pathologic bacteria that are factors in most cases of cystitis are the colon bacillus, the different varieties of staphylococcus, the streptococcus, the tubercle, and the gonococcus.

The Mosquito as a Carrier of Disease.—While accepting, in a general way, current views of the relation of the mosquito to malarial and yellow fevers, J. S. King cannot admit that for the former disease this insect is the only intermediate host for the parasite. He asserts that many of the experiments that have been made by investigators in different parts of the world during the past few years, which are claimed to have established the mosquito as the only intermediate host in the transmission of malarial diseases, have not been conclusive. For it is well known that many persons living in malarial districts can be, and are, exposed year after year to every possible means of contracting malarial fever—through the atmosphere, water, and the mosquito—and yet remain in perfect health; and that healthy persons from non-malarial districts can spend months where malarial fevers are prevailing—mingling with the sick and being exposed to every possible means of contracting the disease—and not have a symptom of malarial trouble.

Gastrointestinal Perforations and Their Diagnosis.—F. G. Connell concludes in the present issue of the *Journal* his studies on this subject. His conclusions are as follows: (1) The previous attempts at an early and accurate diagnosis of perforation of the gastrointestinal tract without opening the abdominal wall have not been adopted. (2) There has been practically no improvement in the method of diagnosing such conditions during the past century. (3) The treatment of the perforation *per se* during the last century has progressed to a state bordering on perfection when compared with the older methods. (4) The diagnosis of gastrointestinal perforations is one of the most important unsolved questions in the domain of abdominal surgery. (5) There is no pathognomonic sign or symptom or group of signs or symptoms of perforation. (6) The only positive method of arriving at a diagnosis to-day is to perform either an exploratory laparotomy or await the development of a peritonitis. (7) To await the development of a peritonitis will reveal the diagnosis too late for the most effectual treatment. (8) Exploratory laparotomy as a routine measure will of necessity result in some cases being needlessly exposed to the many dangers of a major operation. (9) Exploratory laparotomy is not a harmless procedure. (10) The consensus of opinion is in favor of exploratory laparotomy as a choice between two evils. (11) The fact that even the most expert clinicians fail to diagnose perforation in all cases and even diagnose such a condition when it does not exist shows the great need of improvement in diagnostic methods. (12) The diagnosis should be arrived at before the treatment of the perforation is complicated by the presence of a peritonitis. (13) The injection of air or normal salt-solution into the peritoneal cavity and withdrawal of the same for examination will do no harm. (14) Such a procedure will, in many instances, reveal a perforation before any sign or symptom of peritonitis exists. (15) The treatment of the perforation *per se* is simple and satisfactory. (16) The treatment of the complicating peritonitis is multiple and unsatisfactory. The best treatment is prophylactic, *i. e.* early diagnosis and repair of perforation before peritonitis has become established.

The Boston Medical and Surgical Journal, April 2, 1903.

Notes on X-Light.—William Rollins finds that many investigators who have worked with the *x*-light have had greatly impaired eye-sight, as a result from the effect of the light on the crystalline lens. That the author has escaped injury has been due to an early recognition of the dangerous nature of the *x*-light and to having taken certain precautions. These are the following: First axiom: No *x*-light should strike a patient except the smallest beam that will cover the area to be examined, treated, or photographed. Second axiom: No *x*-light should strike the observer. Directions are given for the construction of apparatus to meet the above conditions.

Cæsarean Section for Placenta Prævia.—P. E. Truesdale says that in complete prævia the statistics give an average maternal mortality of 18.9 per cent. and a fetal mortality between 65 and 70 per cent. These results were obtained in maternity hospitals by expert obstetricians, and will probably never be much lowered by any vaginal method of treatment. The mortality figures for Cæsarean section cannot justly be used for comparison, because the operations were performed as a last resource and after alarming hemorrhages had occurred. The author reports a successful case. In conclusion he says that the Cæsarean operation would seem to be the best treatment for placenta prævia, complete or partial, when the child is viable, and when the diameters of the pelvis or the conditions of the soft parts render the operation of dilatation and version, performed with sufficient rapidity to save the child, a dangerous procedure for the mother.

The Clinical Significance of Arteriosclerosis.—Reginald H. Fitz says that a diagnosis of arteriosclerosis is usually made by the physical examination of the accessible arteries and of the heart. The arteries are cord-like, resistent, tortuous, with a ribbed or granular surface. The tension of the pulse is high. The heart gives evidence of hypertrophy of one or both sides by an increased area of dulness, a more powerful apex beat, and an accentuation of the second aortic sound, provided the aortic valve is sufficient. In peripheral arteriosclerosis the physical examination of the accessible arteries is the chief element of diagnosis, but the diagnosis of visceral arteriosclerosis depends first upon the recognition of the

various disturbances of function and then upon the discovery of evidence of central or peripheral arteriosclerosis. In no instance of visceral arteriosclerosis is the diagnosis to be made from the knowledge of disturbance of function alone. The functional disturbances may be due to various causes, one of which is arteriosclerosis, and it is the association of this lesion in the central and peripheral vessels with the symptoms of such disturbed function in an organ which permits the diagnosis of a visceral arteriosclerosis. There are no remedies which can cause this disease to disappear, and the chief benefit of its early discovery comes from the opportunity it gives of warning the patient of the necessity of avoiding mental moral, and physical strain upon blood vessels which already show signs of weakness.

American Medicine, April 4, 1903.

The Influence of Altitude on the Mortality of Pneumonia.—Henry W. Hoagland has gathered a number of statistics which are of interest: There is a total number of 709 cases of pneumonia, 157 deaths, with a death rate of 22.1 per cent., at an average altitude of 6,600 feet, against a percentage of 26.8 at sea level. He thinks that the belief that pneumonia is more fatal in Colorado depends upon the fact that a man with active tuberculosis, with lowered vitality, or one with but one lung, and half of it affected, with a pneumonic consolidation, has very little chance against this disease. In those who are acclimated the disease is no more fatal, and, in fact, from the statistics here presented, it seems manifestly less so at an average altitude of 7,000 feet than at sea level.

Lobar Pneumonia and Its Treatment.—G. Wehrle states that in many cases the drugs so warmly advocated by various authorities cannot be used at all. The best results on the whole seem to come from rational symptomatic treatment. Absolute rest in bed from the very beginning is imperative. The patient should not be allowed to raise himself at all in bed. Anything that will add to the comfort of mind or body is a real and valuable aid to recovery. No visitors at all should be allowed in the sick room. The diet should be nourishing and easily digestible. Milk is both a food and a diuretic. Abundance of plain or medicated water should be given. Enemas of salt solution are also valuable. Tympanites should be relieved by enemas or turpentine stupes. Fever, unless it causes restlessness or remains persistently high, is best left untreated. Circulatory stimulants are often needed, but should be used only when plainly indicated. Strychnine, ammonia, ether, and camphor are most to be depended upon in desperate cases. Many patients will die under any form of treatment. The writer concludes by emphasizing especially the great value of fresh air, plenty of water, absolute rest in bed, and good nursing.

The Use of Compressed Air to Enhance and Prolong the Action of Remedies upon the Cerebrospinal Axis: Synopsis of Experiences in Applying the Method Over Six Thousand Times.—J. Leonard Corning summarizes his conclusions as follows: (1) Limitations of the method.—This plan of treatment is of no use in the management of the inflammatory and degenerative conditions of the cerebrospinal axis. The painful crisis of ataxia may be averted by it, but the progress of the disease is not arrested. Upon such diseases as disseminated sclerosis, spastic, spinal paralysis, poliomyelitis, its influence is nil. In disease of the blood vessels and all cerebral accidents arising therefrom, its use is absolutely counter-indicated. In neuritis this treatment rather augments than diminishes the pain. The same is true of articular rheumatism. (2) Legitimate sphere of application.—Generally speaking, it may be said that cerebral and cerebrospinal affections of a functional character, in which pain, exhaustion, insomnia, or depression are prominent, are the most amenable to this treatment. Here its effects are striking and beyond those obtainable in any other way. Finally, and causally, compressed air, by increasing the pressure in the renal blood vessels, gives rise to diuresis. This effect, obtainable from the air alone, becomes exceedingly pronounced when a diuretic is given, even in insignificant doses.

Medical News, April 4, 1903.

The Significance of Variations in the Internal Secretions.—O. T. Osborne declares that the thyroid gland seems to be the one that has the most to do with the health of the skin, keeping it soft and pliable, and causing the normal amount of insensible perspriation. Suprarenal is a strong cardiac stimulant as well as a vasomotor contractor. Diseased suprarenal glands give the cause of many of the symptoms in Addison's disease, notably the great diminution of vasomotor tension. These glands have something to do with the production of glycogen. What the pituitary secretion means to the system is, in a measure, uncertain. When it becomes disturbed there is almost continuous headache, sometimes excruciating. The glands of the body seem to be more or less interchangeable in their functions; if one is unable to do its work, another seems to take up extra work. The thymus gland contains the largest amount of nuclein, and hence of phosphorus, of any gland of the body and will serve the purpose of any nuclein treatment.

The Prognostic Value of the Diazo-reaction in Pulmonary Tuberculosis.—Francis Carter Wood concludes that: (1) If the urine of a case of pulmonary tuberculosis shows no diazo-reaction and a kidney lesion can be excluded the prognosis is favorable. Only 10 per cent. of the moderately severe cases here recorded gave a reaction, and in a number of these the reaction disappeared on treatment. Early cases not ill enough to apply for hospital treatment do not give the diazo-reaction. (2) If the urine of a case of pulmonary tuberculosis shows an occasional diazo-reaction the prognosis is not necessarily grave as only some 66 per cent of the patients showing an occasional positive reaction die. (3) If the urine of a case of pulmonary tuberculosis shows a continuous strong diazo-reaction the prognosis is very grave, since a large proportion of such cases die within six months. (4) The presence of a diazo-reaction on the first examination of a patient should not debar the case from a thorough trial of climatic treatment in a proper sanatorium.

The Results of Intravenous Injections of Dilute Formalin Solution in Septicæmic Rabbits.—William H. Park reports the results of recent experiments. Even after large doses of formalin the streptococci can still increase in the blood and cause death through septicæmia. Although these experiments are limited in number, still they are so uniform in their outcome that it seems fair to assume that non-lethal formalin injections cannot stop a septicæmia already started in healthy animals. These experiments, as well as others, and the fatal outcome of septicæmia in man after diluted formalin injections should cause us to be guarded in using formalin, and make it necessary to weigh each case injected not only to determine when improvement ensues whether recovery has been promoted, but also when death occurs as to whether harm has been done. An intravenous injection of water plus sodium chloride may prove better than water plus formalin. *Bulletin of the Johns Hopkins Hospital, Mar.-Apr., 1903.*

The Significance of Oxaluria.—J. Bergen Ogden states that oxalic acid may be regarded as a normal constituent of the urine. The amount is very small, usually not exceeding 0.02 gr. in twenty-four hours. It exists in the urine in combination with calcium—calcium oxalate—which is ordinarily held in solution by monosodic acid phosphate, also a normal urinary constituent. Properly, the term oxaluria should be employed in only those cases in which the crystals of calcium oxalate are present in the urine for a considerable period. One important cause of oxaluria is excessive fermentation in the gastrointestinal tract. Another is articles of food containing oxalic acid. Some of these are sorrel, rhubarb, tomatoes, asparagus, spinach, onions, cabbage, and some grapes and apples. A well-marked oxaluria is nearly always accompanied by an increased amount of indoxyl, showing that there is a more or less intimate relation between them. There seems to be a rather close relation between diabetes and an oxaluria. Sometimes a marked oxaluria is an accompaniment of nervous disorders, especially those attended with mental depression, a subacute or chronic prostatitis, and diseases of the heart and lungs.

The Rôle of the Toxins in Inflammations of the Eye.—Robert L. Randolph concludes that: (1) Bacterial toxins, so far as tested, when instilled even for many hours into the healthy conjunctival sac were found incapable of producing inflammation or causing other injury. (2) The same toxins when injected into the tissue of the conjunctiva or into the anterior chamber invariably set up local inflammation, the extent and intensity of the inflammation varying to some degree according to the species of bacterium yielding the toxin. (3) Bacteria which had not previously been proven to produce soluble toxins were found to produce them even in young cultures, and it is suggested that injections of bacterial filtrates into the eye, particularly into the conjunctival tissue, constitute a more delicate biological test for the detection of certain toxins than the tests usually employed for this purpose. (4) The experiments recorded in this paper furnish additional examples, in a comparatively new field, of the importance of toxins in explaining the pathogenic action of bacteria, and likewise emphasize the etiological significance of injuries of the covering membrane of the eye in favoring the action of toxins and of bacteria.

Philadelphia Medical Journal, April 4, 1903.

Subcutaneous Emphysema from Perforation of the Pleura by Extension of Tuberculous Ulceration from the Lung.—Starling Loring reports this case of a mulatto aged thirty-three years. He contracted tuberculosis.

Localized pleurisy developed. In about six weeks he had another attack. About a month later the patient noticed a swelling in the right armpit, which increased and extended inward to the right front of the chest. The next day it reached from the axilla and lower border of the right clavicle downward to the crest of the ilium. The swelling was soft, easily compressible, crackled on pressure, was resonant on percussion, and on auscultation yielded a coarse, crepitant râle with both inspiration and expiration. Punctures allowed the escape of air but did not reduce the swelling. At autopsy there was found a cavity in the upper lobe of the right lung, from which ulceration had extended through the adjacent pleura and the chest wall to the subcutaneous connective tissue.

Impressions of Differences in Practice at Low and High Altitudes.—Will H. Swan reviews this subject and says that as to insomnia, it appears to be the case that most overworked, debilitated, anæmic individuals sleep better on coming to a high altitude, while the full-blooded, high-strung, nervous person sleeps better at sea-level. The writer believes that he sees rather less of so-called biliousness and digestive disorders than while practising at sea-level. As to the occurrence of rheumatism, gout, lithæmia, or uric-acid diathesis, he finds more frequent indications for the salicylates and drugs which are supposed to aid in elimination of uric acid; that there is more often an excess of urates in the urine; that chronic rheumatic affections—especially of a myalgic type seem rather more frequent, while acute articular rheumatism seems less so. In high, dry climates there is increased elimination of water and waste solid products by the skin and lungs. The skin is more active at warm, dry temperatures, while the lungs do more work when it is cold. It is probable that if there are influences in high altitudes which tend to diminish elimination, this can be easily overcome by drinking more water and bathing more frequently. Convalescence after illness in general is apt to be more prompt at high altitudes, because of the greater possibility of being in the open air and sunshine. People who recently come from a low to a high altitude are more easily fatigued.

The Lancet, March 28, 1903.

The Comparative Value of the Mouth, the Rectum, the Urine, the Axilla, and the Groin for Observation of the Temperature.—An elaborate series of observations along this line has been made by F. W. Burton-Fanning and S. G. Champion, with special reference to tuberculosis and to the effects of exercise and other conditions thereon. The article is illustrated by specimen temperature charts, which must be consulted by those interested in the details of the experiments. Concerning the effect on the temperature in tuberculosis of exercise, the authors state that repeated observations were made upon ten patients to ascertain the amount of their reaction to the slight effort entailed in assuming the standing posture. With only one exception a distinct elevation of the rectal temperature has been noted; occasionally as much as a degree's difference has separated the retal temperature of rest and that of standing. It is necessary again to state that the patient must have rested completely beforehand in order that the reaction of standing may be discernible. A patient with arrested pulmonary tuberculosis and wholly free from fever found that his rectal temperature while lying down was 98.9°; he then stood quietly by his chair and the temperature taken each succeeding five minutes read 99.3°, 99.4°, 99.7°, and 99.9°. A rise of one degree, then, had occurred as a consequence of merely standing for 15 minutes. It remained stationary at this point and the patient then resumed the horizontal posture when the temperature was ascertained to have fallen again in ten minutes. As regards the pulse, its frequency was 68 during rest and on standing it rose at once to 80, but while the temperature steadily increased until fifteen minutes had elapsed, the pulse showed no further change. Taking all the observations on the reaction of the rectal temperature to standing the average rise in tuberculosis was 0.5°, the limits being 1.0°, and in one case *nil*.

Medico-legal Post-mortem Examinations.—H. H. Littlejohn lays down the following rules of procedure: (1) The medical inspector should, as a rule, have an opportunity of viewing the body before it is removed from the place of position in which it is found, and in every case the body should be inspected before the clothes are removed. (2) The medical man who attended the deceased before death, or was the first to see him after, should not, as a matter of course, be appointed to make the post-mortem examination, unless he is known to be fully qualified for the duty. (3) A post-mortem should not be made on a case evidently judicial without informing the authorities beforehand, and the warrant of authorization to perform a dissection should always be taken by the inspector to the examination. (4) No one should be allowed to be present at the examination out of mere curiosity or unless specially authorized. (5) Before proceeding to a dissection it is advisable that the examiner should be in possession of information as to the general, and also any special, circumstances of the case, and more particularly in regard to any injury or violence which the deceased may be stated to have received, and as to any known diseased or other condition which may have contributed to the death. (6) The examination should not be commenced without sufficient daylight in prospect to allow of the whole inspection being made without artificial light. (7) The body should be identified by witnesses before the dissection is commenced. (8) Complete notes should be made during the dissection. All measurements should be accurately determined. (9) Injured parts (if possible) all diseased organs or portions of them, and all foreign bodies, should be removed and preserved for further examination. (10) The examination in all cases should be complete, and all the necessary instruments, bottles, etc., should be provided before commencing the dissection.

Treatment of a Formidable Case of Sprue by Diet; the Value of Strawberries.—The patient of F. H. Young was a woman, aged fifty-nine years, who had suffered from influenza and diarrhœa. As these conditions came on the sprue appeared and became so severe as seriously to reduce the patient. She had several attacks of tetany and steadily grew worse on all kinds of diet, but from the time at which strawberries were allowed a marked improvement commenced. The points of interest suggested by the case are summarized by the author as follows: (1) The remarkable change in the condition of the patient after the addition to the diet of strawberries, which distinctly appeared to act as a specific in the disease. Directly strawberries were given it was found possible to increase the bread, which previously could only be given in small quantities, and even then with risk, to practically any extent without there being any return of sprue symptoms. (2) The attacks of tetany, so alarming in this case, are not mentioned as a complication in most textbooks, but it is known that tetany may follow some cases of chronic exhausting diarrhœa. The age of the patient was also unusual for tetany. (3) The uniformity with which the pulse became peculiarly hard, and always then intermittent before the advent of a large fermented motion, was more than a coincidence. So uniform was this that it was always possible to predict the coming event, even though things may have been quite quiescent for some time previously. (4) In the same way the temperature conveyed information not to be disregarded. When the tendency to tetany prevailed a rising temperature always put the author upon his guard and enabled him to adopt timely precautions. There was one curious point about the temperature. A few days after strawberries were commenced the temperature rose slightly in the mornings, reaching 99°, while the evening temperature generally kept lower. This continued for some time after strawberries were stopped. (5) The direction in the textbooks of "milk only" in sprue is not of universal application in advanced cases of the disease. Had it been further continued in the present patient he feels sure that the ending would have been disastrous.

British Medical Journal, March 28, 1903.

Note on the Changes in the Red Cell Produced by the Malignant Tertian Parasite.—J. W. W. Stephens and S. R. Christophers speak of the "stippling" of the red cell produced by the malignant tertain parasite. It is characterized by the fact that: the staining dots are few in number—two to six. They are coarse in size and irregular in outline. Another change is known as the "brassy corpuscle." There are also changes seen in stained films. The corpuscles containing the developed, malignant, tertian parasites present minute clefts or spots, scattered over the cell, staining slightly with hæmatein.

A Case of the Form of Chronic Joint Disease in Children Described by Still.—F. Parkes Weber reports this case, which was a typical example of the articular affection in children described by Still. There was an attack of endocarditis and the initial valve was affected. The knee and elbow-joints became enlarged, but the most striking features of the case were the symmetrical swellings about the articulations of the hands and feet, and the stiffness in the cervical region of the spinal column. The spleen, liver and lymphatic glands in neck, axillæ, and groins were enlarged. The results in this case seem to show that the rheumatoid articular affection in children described by Still is sometimes practically recovered from. The most important part of treatment has consisted in keeping the child away from the unsatisfactory conditions of its own home, care in regard to diet, etc.

The Diagnostic Value of Blood Counts in Malarial and Other Fevers.—T. H. Delany, after giving the tables rep-

resenting his work in this line, says that if the diagnosis of malaria can be made in over 90 per cent. of cases by the blood count against 17 per cent. by the parasitic test, there can be no question as to which is the superior method. A reduction of the white corpuscles to 1,500 or less is of grave prognostic value. Large doses of quinine hypodermically will alone save the patients in such cases. Leucocytosis in malaria seems to be comparatively rare. The writer th n shows the value of blood counts in the diagnosis of post-operative and post-puerperal fevers in the tropics and in the diagnosis of liver abscess from malaria.

A Demonstration on Some Experiments on the Nature and Specific Treatment of Hay Fever.—Felix Semon concludes that: There can be no doubt that Professor Dunbar has succeeded in extracting from the pollen of certain grasses (maize, wheat, rye, etc.) a toxin which, when instilled into the eyes or nostrils of people predisposed to hay fever, produces in these parts the characteristic subjective and objective symptoms of the disease. The toxin, when injected into the eyes or nostrils of people not predisposed, produced, in the great majority of cases, no symptoms whatsoever, but it appears as if there were instances of transition in which, although the persons experimented upon never suffer from typical hay fever, they are yet more susceptible to the influence of the toxin than the ordinary run of people. The effects of the toxin in people suffering from hay fever are variable in intensity. Dunbar's antitoxin produced immediate disappearance of the subjective, and after a few minutes great amelioration of the objective symptoms. The effects of the antitoxin are sometimes sufficient to prevent a rea - pearance of the subjective symptoms, but sometimes repeated instillations of the antitoxin were required to produce ultimately the return to normal conditions. Although the writer does not believe in raising pre ature hopes, still he thinks a most important discovery has been made which he hopes will ultimately lead to the development of an effectual specific treatment of this troublesome affection.

Berliner klinische Wochenschrift, March 9, 1903.

Traumatic Albuminuria.—Fr. Engel reports a case to show that all uminuria may occur from simple traumatism. The patient was twenty-two years of age, and shortly before the accident, which was a fall from a horse, had successfully passed a life-insurance examination. The fall was followed by much pain and stiffness of the back. The examination of the urine was first made one week thereafter and showed albumin by Heller's test and sugar by Nylander's Frequent examinations were subsequently made, but all umin was never again detected, although the glycosuria persisted in traces. Casts were never found.

Does Mercury Cause Tabes?—Paul Cohn says that there is no evidence to show that it does. He reports 117 cases of tabes; of these 43 had previously had syphilis. Fifteen had never been treated with mercury. Twenty-eight had taken the drug but had not followed out a systematic mercurial treatment. In most instances only small and infrequent doses had been taken. Those patients who had never had syphilis had, however, passed through some of the infectious diseases, notably influenza and typhoid fever. It is evident that while syphilis may be an etiological factor in tabes it is not the only one, and that other infectious diseases play a certain part in its causations.

Berliner klinische Wochenschrift, March 10, 1903

Traumatic Albuminuria.—H. Senator refers to Fr. Engel's recent article upon traumatic nephritis in the *Berliner klinische Wochenschrift*, 1903, No. 10 The latter author says that hitherto traumatism has not been considered among the etiological factors of albuminuria or nephritis. This is not correct, for, in Senator's book on diseases of the kidneys (second edition) the following passage occurs: "It is not certain whether traumatism can cause nephritis. The symptoms such as hæmaturia, albuminuria, and cylindruria, which frequently appear after traumatism, do not necessarily indicate the presence of a nephritis since they could be caused by a rupture of the renal vessels, or a mutilation of the kidney substance. It is possible, however, that traumatism of the kidney may lead to necros s in this organ, and that, as the result of such, reactive inflammations may arise."

Carcinoma and Diabetes.—J. Boas reports 366 cases of intestinal carcinoma in twelve of which carcinoma and diabetes were concurrent diseases. In five the diabetes preceded the carcinoma. The influence of the diabetes upon the course of the carcinoma is varied, depending upon the grade of the former. If a carcinoma develops during a diabetes of marked intensity, such a tumor usually runs a rapid and exceedingly malignant course; while, on the other hand, if the diab tes is of low grade the intensity of the carcinoma is abated. The influence of the carcinoma upon the diabetes is also varied. In many instances such an influence is favorable, the intensity of the diabetes markedly lessening, but in other instances the reverse is the case, and the diabetes becomes much exaggerated. The factors which are responsible for these variations are not at present known. In diabetics who develop carcinoma, and in all cases in which these diseases are associated operative treatment for the tumor should be deferred until the urine is sugar free.

Deutsche medicinische Wochenschrift, March 12, 1903.

Antistaphylococcus Serum.—Pröscher has obtained a serum which completely protects rabbits against five to seven times the fatal dose of virulent staphylococcus cultures. The serum was obtained by submitting goats to successive inoculations of virulent staphylococcus bouillon cultures. This serum also agglutinates such cultures in 1 to 2,560 dilution. It has not as yet been tried upon human subjects, but if found efficient in such, its wide scope of usefulness is obvious.

Identity of Bovine and Human Tuberculosis.—Tro'e reports a case which is unique, and which adds evidence in favor of the view that human and bovine tubercle bacilli are identical species. The patient was a young healthy male, who gave no hereditary or personal history of tuberculosis. He was inoculated with bovine tuberculosis on the hand, and a typical lupus lesion developed at the site of inoculation. Subsequ ntly the lymphatic glands which drain the involved region became tubercul us, and, in the course of time, many other lymphatic glands throughout the body bec me similarly affected. Those who dispute the identity of bovine and human tuberculosis have always contended that those who become inoculated with bovine tuberculosis never developed tuberculosis in other regions of the body, and especially that the lymphatic glands never became tubercul us. This is the first case reported in which such involvement occurred, and it at least shows that the same is possible

Münchener medicinische Wochenschrift, March 10, 1903.

Relations between Epilepsy and Migraine.—William Strohmayer concludes from a study of the material available in Binswanger's clinic in Jena, that migra ne and epilepsy often coexist in the same patient. Usually migraine appears first to be followed sooner or later by epilepsy. No case has, however, been observed by the author in which one of these diseases was transformed into the other, or in which one was substituted for the other. When such was apparently the case, it is evident that the migraine was only a symptom of the epileptic condition or that the epilepsy developed as an independent disease, in addition to the migraine. In atypical cases it was difficult to decide whether the epilepsy or the migraine was the primary condition.

Banti's Disease and An æmia Splenica.—F. Marchand does note that splenomegalia is the cause of the cirrhotic changes which develop in the liver in the latter stages of Banti's disease, but that such cirrhotic changes are due to other causes, as, for example, congenital syphilis or alcohol. Two cases are reported, one of Banti's disease and the other of anæmia splenica. In the former, the liver cirrhosis either preceded or arose simultaneous with the splenic condition. The case was operated upon for the ascites, and thereafter the cirrhosis became non-progressive, and at death autopsy showed that the liver condition was not active. In the second case, the patient became tubercul us and died. At autopsy no cirrhotic lesions were found in the liver, although the patient had, for some years, suffered from splenomegalia.

Ovariotomy During Pregnancy.—Willi Thomass reports the case of a woman upon whom ovariotomy was performed during the third month of pregnancy. Abortion followed two days after the operation. The operation was performed, not from necessity, but on the earnest solicitations of the patient. Previous to the operation no tendency to abortion had been detected, and the patient had already passed successfully through four pregnancies since the ovarian tumor had first been discovered. The operation was prolonged on account of numerous adhesions and considerable blood was lost, this probably accounts for the early abortion. From this case, and a résumé of those recently reported by Graefe, it is evident that ovariotomy performed during pregnancy is very liable to be followed by abortion, and that the operation should not then be performed unless urgent symptoms require.

Disinfecting Power of the Old and New Mercurial Preparations and Phenol.—Fritz Hammer has tested experimentally the comparative disinfecting power against anthrax and

staphylococci cultures of certain mercurial and phenol preparations. The mercurial preparations were the sublimate (1 and 3 per cent. solutions) sublamin (1, 3, and 5 per cent. solutions), and hydrarg. oxycyanatum (¼, ½, and 1 per cent. solutions). Those of phenol were carbol (1, 3 and 5 per cent. solutions), cresol (1, 3. and 5 per cent. solutions), lysol (1, 3 and 5 per cent. solutions), cresol soap solution (1, 3, and 10 per cent. solutions), bacillol (1, 3, and 5 per cent. solutions). and lysoform (1, 3. and 5 per cent. solutions) The sublimate solutions, even those of 1 per cent., showed much greater bactericidal power than any of the other substances tested. The phenol preparations possessed very little power, growth taking place in all the tests. The time of exposure to the disinfectants was five fifteen, and sixty minutes. As a rule, the growth recurred more quickly in the anthrax cultures than in those of the staphylococci.

French and Italian Journals.

Ovarian Cyst in a Small Girl of Eight Years; Recovery.—Delassus reports this case, the chief interest of which lies in the extreme youth of the patient The operation offers nothing of particular interest, and the results were excellent. The physician had detected the tumor two years before. The tumor reached to the umbilicus A great part of it was cystic. Before operation it was thought that it was a cystic sarcoma or a dermoid cyst. In reality the tumor was mixed, and in its midst was cartilaginous tissue. It weighed 800 grams.—*Journal des Sciences Médicales de Lille*, March 7, 1903.

Appendicitis and Opium.—Krafft concludes that: Surgeons do not employ opium as the treatment of perappendicitis, but simply to calm the pain and peristalsis before operation. Purgatives and injections are dangerous because the peritoneum, always inflamed in per append.-citis, can only be disturbed in its process of encapsulating the trouble, if it is shaken up by irrigations either by mouth or rectum. In periappendicitis, operation is the only rational treatment. Tenderness, acute and localized, at McBurney's point or elsewhere in the case of "cæcum migrans" is the only symptom on which we can count in the beginning of an appendicitis.—*Revue Médicale de la Suisse Romande*, February 20, 1903.

Hysterical Fever.—G. B. Ughetti reports several cases of this not very frequent affection. The hyperpyrexia appears to be the only constant symptom, and strangely enough, hysterical attacks do not seem to occur during the rise of temperature. One of the most important distinctions between hysterical fevers and those due to infection is the dissociation of the three phenomena—temperature, pulse, and respiration. Yet this sign is not always present. Nearly every type of fever is simulated by this affection, the most insidious being that which simulates typhoid fever.—*La Riforma Medica*, March 4, 1903.

Histological Changes in the Spinal Cord Due to Local Injections of Cultures of Staphylococcus.—Vittorio Martinelli, concludes, from his experimental researches, that the injection of very virulent cultures of the staphylococcus produces a limited local lesion the character of which is chiefly that of a necrosis and only secondarily that of a suppurative inflammatory process. The microorganisms which are injected disappear rapidly from the site of injection, owing to cellular phagocytosis, and even in fatal cases but few cocci can be found *in situ*.—*Giornale della Associazione Napoletana di Medici e Naturalisti*, November-December, 1902.

Tumors of the Larynx and of the Velum Palati.—Garel presented a patient with respiratory embarrassment, spasms, and a peculiar vocal timbre. Examination discovered a large tumor of the size of a nut masking the whole glottis. Light swelling movements at each respiration first gave rise to the suspicion that the tumor was pediculated. Garel preferred its extraction by the natural ways to surgical intervention. The tumor was removed by electricity. It was a fibroma. The writer has removed two other rare tumors from the velum palati, one a simple lipoma, and the other a mixed growth of congenital origin.—*Lyon Médical*, March 1, 1903.

Pustular Acne of the Face.—Leredde says that the remedy most employed for this affection is sulphur. The pastes are much used in the treatment of acne. They consist of a mixture of powders and fats, made up to a firm consistence. The value of the excipient lies in the fact that the proportion of active substance which is incorporated in it can be increased or diminished, without increasing or diminishing to the same extent the efficiency of the preparation. A pomatum used in acne consists of: precipitated sulphur, 5 grams; vaselin, 75 grams; lanolin, 20 grams; calomel, 2 gr. 50. Sometimes even exfoliation is necessary. General treatment should be given at the same time.—*Journal des Practiciens*, March 14, 1903.

Diagnosis of Appendicitis from Blood Examination.—Lamy states that the researches of modern workers show that leucocytosis does not appear exclusively in the suppurative forms of appendicitis. In the milder forms which terminate by resolution, the number of white corpuscles reaches 15,000 to 20,000 per cubic millimeter at the moment of the acute crisis. This hyperleucocytosis is very fleeting. It lasts only from two to four days. On the contrary, in the grave forms, when suppuration is established, the number of leucocytes exceeds 25,000, even reaches 30,000, 40,000, and more. And this condition persists a long time. In every case, initial leucocytosis is the rule.—*Gazette des Hôpitaux Civil et Militaires*, March 10, 1903.

The Results of the Ligature of Steno's Duct.—V. Marzocchi and E. Bizzozero concludes, from their experiments on animals, that the ligature of Steno's duct does not lead to the formation of cysts. The lumen of the acini and of the duct becomes dilated and the epithelial cells are changed. Immediately after the operation the gland is found to be invaded by leucocytes with polymorphous nuclei, which gradually decrease, but do not entirely disappear, even after the lapse of sixty-five days. Reactionary process on the part of the connective tissue is very slow in becoming established, and does not lead to sclerosis sixty-five days after the operation.—*Gazzetta Medica Lombarda*, March 15, 1903.

A Case of Hepatitis with Grave Icterus in an Infant Nursed by a Nephritic Mother.—Dante Pacchioni reports the fatal case of an infant of four months with hepatitis. The mother had always been healthy, but in the last month of pregnancy had suffered from œdema, and albumin had been found in the urine. At the time of the child's death she still had slight albuminuria, with a few hyaline and granular casts and scattered renal cells. The author considers it rational to suppose that the toxic substances excreted by the mammary gland of a nephritic woman might produce various morbid symptoms in the infant (hæmolytic, phlogistic for certain tissues, convulsive, tetanic, dystrophic, etc.), according to the nature of the toxin and the individual predisposition of the infant's tissues.—*Rivista di Clinica Pediatrica*, March, 1903.

Chronic Recurrent Osteomyelitis.—Deroeque describes a sequestrum, 5 or 6 cm. in length, which was taken from a patient operated on by him. The patient was a man of forty-nine years, who at the age of fourteen years had an osteomyelitis of the upper extremity of the right tibia, accompanied by considerable fever. At the end of six weeks several small sequestra were eliminated. Suppuration ceased at the end of two months. Again, at eighteen years of age, there was another attack following trauma; at thirty-nine years another attack occurred with great pain. Again, this last attack was accompanied by such pain that an operation was performed. An abscess was discovered and the sequestrum mentioned above was removed.—*La Revue Médicale de Normandie*, February 25, 1903.

Treatment of Lead Colic by Electrical Injection.—M. L. Galliard presents most encouraging results from this treatment. The first case he reports was a patient of thirty-six years, a worker in metals. He had not had a bowel movement for five days. No gas had been passed for thirty-six hours. This treatment was followed so quickly by relief, that the writer determined to institute it systematically in all cases in which coprostasis was resistant to simple or purgative injections. In a foundryman of thirty-two years, who had not had a passage for six days, and who had vomited bile, a single electrical injection resulted in rapid recovery, as in the former case. Other cases with results equally as successful are reported. This treatment allows the complete suppression of purgatives, which are attended by multiple inconveniences.—*Le Bulletin Médical*, March 21, 1903.

Alimentary Régime in Muco-Membranous Enterocolitis.—Froussard declares that diet plays an important rôle in this affection. He treats the subject very thoroughly and considers not only foods, but their preparation. Butchers' meats and fowl may be eaten provided they are fresh, tender, and not infiltrated with fat. Fat is badly digested Fish with lean meat may be recommended. All of the crustaceans and shell fish should be rejected. Perhaps the oyster might be excepted. Green vegetables are as a rule, badly digested Starchy vegetables are useful. Often milk is badly digested when given in the absolute milk régime. Fruits in general may be taken. Pure water is the best beverage. Butchers' meat should be roasted or broiled. Fowls should be roasted. Yolks of eggs and very fresh butter ought to replace fats of animals or vegetable origin in ordinary use.—*Gazette des Hôpitaux Civils et Militaires*, March 17, 1903

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held April 2, 1903.

ANDREW H. SMITH, M.D., PRESIDENT.

Chronic Middle-ear Suppuration.—This was the subject for the evening's discussion, the meeting being in charge of the Section on Otology.

Symptomatology and Diagnosis of the Complications.—DR. T. PASSMORE BERENS read this paper. He said that cases of suppuration of the middle ear were common. Thus, out of 25,667 cases of ear diseases at the Manhattan Eye and Ear Hospital during the last six years, 7,336 were cases of suppuration of the middle ear. The suppuration was considered to be chronic when it had persisted actively for six months. It generally began as an acute suppuration, which in turn originated, as a rule, in conditions of the general health causing a lowering of the natural resistance of the mucous membranes to infection with pathogenic microorganisms. Chronic suppuration of the middle ear very commonly resulted from the neglect of acute conditions, or secondarily as a result of destruction of the mucous membrane and periosteum with erosions of the bone, or by the formation of granulation tissue. Extension of infection from the ear into the brain often took place through the tympanum and the mastoid antrum into the middle cerebral fossa. The complications of chronic suppuration of the middle ear were chiefly deafness, suppurative mastoiditis, osteosclerosis of the mastoid, facial paralysis, vertigo, leptomeningitis, sinus thrombosis, and brain abscess. The latter was only considered in the present discussion. The symptoms of extradural abscess were said not to be constant. There was usually pain on pressure over the mastoid antrum and a profuse discharge from the ear, although the latter symptom might be entirely wanting When the arachnoid was once affected, the infection spread rapidly, and might eventually involve the whole subdural space. The rapidity of this process was remarkable, frequently only a few hours being required. The tissues were anæmic, and there was marked dilatation of the veins, which were surrounded by an exudate which rapidly degenerated into pus. The symptoms of purulent leptomeningitis in the early stages were variable, being insidious in some cases and marked and sudden in others. Usually there were headache and pain referred to the side of the diseased ear, associated with vomiting and retraction of the abdomen. There was, ordinarily, a decided elevation of temperature accompanied by chilliness. The cranial nerves were usually affected. General convulsions were not unusual, and spasms or rigidity of different groups of muscles were common, while optic neuritis, squint and intolerance to light and sound were familiar symptoms. Meningitis serosa was the serous form of leptomeningitis, and was due to hyperæmia, followed by an exudation of serum containing a few leucocytes, but no pathogenic microorganisms. The effusion of fluid might be so rapid and abundant as to cause pressure on the brain, and even death. The symptoms were those of intracerebral pressure. The diagnosis was confirmed by lumbar puncture or puncture through the dura under aseptic precautions during operation on the temporal bone. The prognosis was fair in cases operated upon early. Septic thrombosis into the cranial sinuses was usually the result of a spread of the process, by continuity. The size of the thrombosis varied; at times it might extend even down into the innominate vein. A leucocyte exudate formed around the vein, giving rise to phlebitis or periphlebitis. When this occurred in the brain it led to septic leptomeningitis. Pain on pressure was usually present at some point on the mastoid and at the upper end of the internal jugular vein. The commonly quoted symptom of a cord-like swelling in the neck along the course of the jugular vein was usually absent. Choked disk was frequently present, as was optic neuritis. In thrombosis of the cavernous sinus there was exophthalmos. Disease in the jugular bulb might give rise to tortico lis, paralysis of the pharyngeal muscles, and hoarseness. The general symptoms were headache marked digestive disturbance and foul, heavy odor to the breath. Chills were always present, although they might not be marked in the early stages. They were followed by high fever, the temperature frequently rising above 105°F. They were followed by a profuse and prostating sweat. The temperature was remittent in type. The pulse was rapid and became weaker as the disease advanced. The patient died either from toxæmia or from metastases into various organs. Examination of the ears would usually aid in differentiating from malaria and typhoid fever. From pneumonia, the physical signs would aid in making the diagnosis. From meningitis, it was differentiated by the absence of involvement of the cranial nerves and absence of delirium. Cases operated upon early usually did well. Abscess of the brain or cerebellum was not uncommon. If the infection were by way of the blood or lymph channels it was usually caused by a septic embolus or thrombus. The most frequent location for brain abscess was in the temperosphenoidal lobe, and the next most frequent site was in the cerebellum. Generally speaking, there was only one abscess. In the encapsulated form the symptoms of the early stages were so slight as usually to pass unnoticed. The general symptoms of brain abscess were headache, disturbance of the digestive system, sensations of chilliness, propulsive vomiting with no relation to the taking of food, and not preceded by nausea. The respirations were slow, especially in cerebellar abscess. The temperature was usually subnormal or nearly normal until the last stages, when it would suddenly rise to 108°F. or higher. The pulse was slow until the late stages of the disease Vertigo was present There was a tendency to drowsiness, but the patient could be easily aroused until late in the disease. Cerebration was slow. As the disease progressed, drowsiness deepened into coma, and emaciation was marked and rapidly progressive. Convulsions were rarely present, and localizing symptoms might be few, owing to the fact that motor areas frequently escaped. In cerebellar abscess there were usually occipital headache, stiffness of the muscles of the neck, vertigo, staggering gait, and sometimes nystagmus.

Treatment of the Complications.—Dr. JAMES F. MCKERNON presented this paper. He said that one of the first and most frequent complications was a more or less extensive destruction of the membrana tympani. A careful examination of the nose and nasopharynx should be made, and if any obstructions were found there they should be removed. It was a cardinal principle to maintain cleanliness of the structures to be healed, and to apply an astringent solution to the edges of the perforation. The favorite remedy was a solution of silver nitrate, varying in strength from a very weak to a saturated solution. This application should be followed by an insufflation of some drying powder, such as boric acid, aristol, or acetanilid. Subsequently the hearing should be improved by the use of catheter insufflation and vaporization in adults, and of the Politzer bag in children. Fungoid masses should be removed by means of the curette after cocainization of the base. In some cases the opening in the membrane was slow in healing, and the process should then be hastened by the use of collodion, or by the gumming of a bit of paper over the opening. After doing an ossiculectomy extreme care should be exercised to remove all diseased tissue in or around the tympanic opening of the Eustachian tube. Furuncle of the external auditory canal was frequently observed during a purulent discharge from the middle ear. Free incision, followed by curetting and drainage, was the most rapid method of effecting a cure.

Mastoiditis.—Mastoiditis might be met with in either the acute or the chronic form. At the outset a careful examination of the middle ear should be made, and if the drum membrane was found to be bulging a free incision should be made in this membrane to permit drainage. If there was much tenderness over the mastoid antrum or tip, the ice-coil should be applied for twenty-four hours, and the auditory canal irrigated every three hours with a very weak solution of bichloride. If some diminution of tenderness were observed after twenty-four hours, the ice might be continued for twelve hours more. It was most important to make a bacteriological examination of the discharge from the middle ear. When this examination showed the presence of the streptococcus, one might feel almost sure that operation would be demanded. The antrum should be entered first and a free communication established between it and the middle ear. Careful search should be made for cellular structures. The removal of the first dressing could be made comparatively painless if a piece of sterile rubber tissue were button-holed and approximated to the bony cavity before inserting the gauze.

Subperiosteal Abscess.—In cases of subperiosteal abscess it was not sufficient merely to open the subperiosteal accumulation, for in thirty-one cases of this kind which he had treated in children, varying in age from five weeks to eight years, pus was found in the mastoid process thirty times.

Pachymeningitis—Pachymeningitis was a common complication of mastoid abscess. The pus and granulations should be removed. When the dura was found to be covered with healthy granulations they should not be molested, as this was nature's method of effecting a cure.

Sinus Thrombosis.—Sinus thrombosis was most commonly observed in the sigmoid sinus. The first step in the treatment was a thorough exposure of the sinus and a flushing of the field with absolute alcohol to insure sterilization. The anterior wall of the sinus should be incised rather than punctured with an aspirating needle, for the latter method had been found misleading. If a clot were present, a freer incision should be made, and the thrombus removed. Hemorrhage was controlled by the packing in of gauze. In about one-half of the uncomplicated cases the return circulation could be reëstablished. When the sinus did not contain pus and the symptoms did not point strongly to a jugular involvement, it was better not to carry the operation any further, even though there was no return current of blood. In all of the cases the lower end of the sinus and bulb should be exposed, as here the trouble was very apt to be located. If, on opening the sinus, a disintegrated clot were found, or else pus, the clavicle should be resected, and the internal jugular vein should be removed, provided the patient's condition would permit. Enlarged glands found in the course of the dissection should be removed. The wound in the neck should be flushed with hot saline solution, and then nearly closed with a continuous silk suture. The inferior petrosal sinus was quite frequently thrombosed in connection with thrombosis of the sigmoid sinus. A thrombosis of the cavernous sinus was almost invariably fatal.

Brain Abscess.—About 37 per cent. of all cases of brain abscess were of otitic origin. When there was an accumulation of pus just beneath the dura, the latter would be found of a darker color than normal. After opening the dura silk sutures should be used as retractors. For exploring the brain, he preferred the use of the scalpel and finger. When pus was found a sufficient opening should be made and wick drainage employed. After three or four days the wick should be renewed. When there were no distinct localizing symptoms, it was well to make the opening one inch above the center of the bony meatus. In all cases the openings should be made as nearly as possible on a level with the floor of the lobe, which it was desired to drain. In cases of suspected cerebellar abscess the opening should be made one inch and a half behind the center of the bony meatus and one-third of an inch below that point. Metastatic abscesses in various parts of the body should be treated on general surgical principles.

Facial Paralysis.—Facial paralysis was by no means uncommon following middle-ear suppuration. Absolute rest and frequent purgation were important elements in the treatment. When paralysis appeared several days after an operation for the removal of dead bone and there was no solution of continuity around the canal the paralysis could be explained either by concussion over the canal at the time of the operation, or by later inflammation, or by injury of the facial branch of the chorda tympani This form of paralysis would recover spontaneously The use of the interrupted galvanic current and appropriate tonic treatment were important adjuvants Vertigo following partial occlusion of the Eustachian tube was often troublesome, and could be quickly relieved by inflation of the tube. If treated early and properly, an acute suppurative process in the middle ear should never reach the chronic stage.

Dr. Robert Abbé said it was most interesting to note the changes that had taken place in surgical work in the last thirty years. Formerly the hospital wards were filled with erysipelas, and second to that the great bugbear was pyæmia. The great causes of pyæmia were appendicitis and middle-ear suppuration. The advances made in the treatment of these conditions had very largely eliminated pyæmia. No matter how grave a case of pyæmia might appear to be when first seen a thorough removal of the source of infection in the mastoid not infrequently resulted in a cure. He had been impressed with the disposition of the general practitioner to delay operation if there was no tenderness or œdema of the mastoid, even though there were fever and other evidences of mastoid infection. In such cases if the disease were of long standing the mastoid was apt to be so eburnated that it was difficult to chisel through it. These cases usually presented a maximum of symptoms with a minimum of external evidence. He was not disposed to agree with Dr. McKernon as to the wisdom of partially suturing the wound of the jugular vein; it seemed to him far better to leave such a wound open, protected only by iodoform gauze. A wound that had been allowed to granulate for a few days and was then closed by strapping left a scar that was almost as small as in cases in which the wound had been sutured primarily.

Dr. William M. Leszinsky deplored the tendency to postpone the calling of the neurologist in consultation until the patient was comatose or moribund. Earlier consultation of this kind, he felt, would often throw much light upon the diagnosis. He did not see nearly as many abscesses of the brain or cases of meningitis due to otitic disease as he had done ten years ago. In view of the fact that a cerebral abscess was generally confined to either the temperosphenoidal lobe or the cerebellum, and in view of the fact that both of these points were classified as among the latent points of the brain, or those at which a lesion was non-localizable it was easy to see how difficult it was even for the neurologist, to make a correct diagnosis. It was not always easy to make a differential diagnosis between meningitis and abscess. Slowness of the pulse and a considerable elevation of temperature were observed in meningitis. In abscess of the brain there were often remissions, whereas in meningitis the disease usually progresses steadily. Rigidity of the muscles of the back of the neck were also apt to be misleading. Such rigidity was not apt to be found in cerebellar abscess unless this was associated with meningitis. He did not think lumbar puncture was of material assistance in cases of serious meningitis, although it was of value in other forms of meningitis. Several observers had maintained that there was danger connected with this procedure because of the reaction upon the brain. In his opinion the otologist was not justified in making indiscriminate explorations of the brain unless the symptoms were pretty clearly defined.

With regard to paralysis, Dr. Leszynsky said that an ounce of prevention was better than many pounds of cure. The only way of determining whether the nerve was degenerated or not was by the absence of irritability in the nerve and muscle when irritated by the faradic current. If at the end of ten days or two weeks the faradic irritability were abolished, it was an open question whether or not the use of the affected muscles would be recovered. He had previously pointed out that the determination of the occurrence of this degeneration could be made by the faradic as well as by the galvanic current.

Dr. Emil Gruening spoke of the anatomical conformation of the temporal bone and its bearing upon the diseases of the ear. It was known, he said, that at times the jugular bulb was very large, so that it encroached upon the floor of the tympanic cavity. In an ordinary case of otitis media it was not uncommon to find a sudden development of urgent symptoms. The jugular bulb lay much higher than the lowest part of the lateral sinus. The anatomical conformation of the mastoid often determined the course of the disease. He had not found the bacteriological examinations of great assistance. If there were a large antrum and large cells there would be no fever or headache, and only a slight tenderness. After a few weeks a few enlarged glands would be observed. These were most dangerous cases, because suddenly the pus would escape and give rise to very severe symptoms.

Dr. Wendell C. Phillips said he fully believed the truth of the statement already made, *i. e.* that if acute suppuration of the middle ear were properly treated there would be no chronic suppuration. This statement reflected very gravely upon the defective teaching in the undergraduate colleges, at least in years past. He was of the opinion that abortive measures were practically useless in any case of mastoiditis developing in a case of chronic suppuration. There had been a long-standing necrotic process in the tympanic cavity, so that only a slight increase in the inflammatory process was necessary to cause serious results. Bacteriological examinations of the discharge in acute cases were important, but in the chronic cases it could hardly be expected to have the same value. Early operation not only robbed this disease of most of its dangers, but gave the patient the best results as regards hearing. He had not found elevation of temperature of much importance in adults suffering from this affection. He did not think that any cases of general septic meningitis recovered, and so firmly was he convinced of this that in such cases he would not torture the patient by operation. He had recently been in correspondence with some life insurance medical examiners and had learned in this way that most of these examiners were so firmly convinced that chronic suppuration of the middle ear was dangerous that they either rejected such applicants for life insurance altogether or else required them to pay a higher premium.

Dr. Berens said that the temperature was of very little value in the classes of cases under discussion, even the most dangerous and extensive destructive processes often being present with little or no fever.

Dr. McKernon said that he had had no occasion to regret the policy of partially suturing the jugular wound, and the resulting scar, according to his experience, was much finer than when the wound was allowed to granulate.

Malta Fever.—(1) There occurs in the tropics and subtropics a fever which may resemble in its acute stage either typhoid or malaria, and in its chronic stage articular rheumatism, caused by the micrococcus meli ensis. (2) There are no pathognomonic symptoms of Malta fever. The symptoms observed are so inconstant and confusing that no one of them can be said to be typical of the disease. (3) A differential diagnosis of this fever is almost impossible in the majority of cases without the aid of the microscope and the serum test.—*Craig, American Journal of the Medical Sciences.*

NEW YORK ACADEMY OF MEDICINE.

SECTION ON OBSTETRICS AND GYNECOLOGY.

Stated Meeting, Held March 26, 1903.

L. J. Ladinski, M.D., Chairman.

Deciduoma Malignum.—Dr. S. Marx presented a specimen of this condition. He said that the diagnosis had been made on the clinical history before a microscopical examination had been made. From the time of the first examination until the time of the radical operation no hemorrhage occurred. The patient was a woman of twenty-nine years, who had been married eight or nine years but had never before been pregnant. Six weeks before coming under observation, on March 23, she gave birth spontaneously to a three-and-a-half-months' fœtus, and did not quite recover from it before hemorrhage became so severe that her family physician thoroughly curetted her uterus. Despite this the hemorrhage became profuse, and she almost went into collapse. The speaker then examined her, and found what he at first thought was an organized uterine polyp. Her condition was so bad that an intravenous infusion was given, and then she was placed in hospital and this mass removed. She improved very rapidly in the course of the next three months, but then the hemorrhage recurred. Examination at that time showed the cervix open and a very large mass at the spot from which he had removed the first mass. In view of this history he made the diagnosis of deciduoma malignum, and then removed scrapings and submitted them to a competent pathologist, who confirmed the diagnosis. Hysterectomy was performed upon her sixteen days ago. She did well for a few days, but at the end of the first week suffered from exceedingly severe headache, which led him to suspect a metastasis in the brain. However, a neurologist was consulted, and expressed the opinion that the headache was merely the result of the anæmia, and appropriate treatment materially modified the headache. The pathologist said that the deciduoma was exceedingly superficial, and that the prognosis was good.

Pyosalpinx Complicating Pregnancy.—Dr. G. H. Balleray presented several specimens. The first was a tube and ovary, removed from a woman who was four months pregnant, and suffering from acute peritonitis. She had had four self-induced abortions in the preceding two years. Her pain at the time of examination was intense, and was associated with vomiting and high temperature. On opening the abdomen free pus was found, and the tube on the left side contained pus and the ovary on that side was cystic. There was a small perforation in the tube. The latter was removed, the parts swabbed with gauze, and the abdomen closed. She convalesced rapidly and did not abort until two weeks afterward. The fœtus was macerated and the membranes were retained.

Pyosalpinx and Operation During Acute Gonorrhœa.—The next specimen was removed from a patient suffering from pyosalpinx and acute gonorrhœa. The temperature was about 103° F., and the pulse 120. On opening the abdomen both tubes were found filled with pus. On separating the adhesions three or four ounces of free pus welled up, but the general peritoneal cavity was protected by gauze pads.

Hysterectomy for Malignant Disease and Procidentia.—The third specimen was a uterus, removed one week ago from a woman of fifty-seven. She had passed the menopause ten years previously. A small growth was found on the cervix, which proved to be malignant. The patient was rapidly convalescing. The next specimen was a tube and ovary removed from a case of puerperal sepsis. Considerable difficulty was experienced at the operation because of the number and density of the adhesions. The patient made a good recovery.

A Case of Cæsarean Section.—Dr. Balleray also reported this case. The patient, a woman of thirty-two,

was admitted to the Paterson General Hospital on February 14, 1903, with a transverse presentation of the fœtus and a marked pelvic deformity. She was a dwarf four feet and eight inches high with a marked humpback. The elastic ligature was dispensed with in the operation, and the uterine arteries were controlled by manual pressure. The uterus was turned out and the usual incision made through the uterine wall. The placenta was directly under the upper part of the incision. The child was quickly extracted, and the membranes delivered. The uterine cavity was then wiped out with iodoform gauze and the wound in the uterus closed by sutures. The abdominal wound was closed by through-and-through sutures of silkworm gut. The duration of the operation was twenty-seven minutes. The infant was a female weighing seven pounds, and although asphyxiated at birth it was resuscitated. According to measurements taken by the house surgeon, the distance between the anterior superior spines in this woman's pelvis was 25 cm.; between the crests, 27 cm.; between the trochanters, 27.5 cm., and between the ischial tuberosities, 6 cm., and the external conjugate was 15 cm.

Dr. MARX said that if the pelvic measurements had been correctly stated he would look upon this as an obliquely tilted ovate pelvis of Naegele of the funnel-shaped type. He was glad that the elastic ligature was not used, because he had seen very severe and extensive injury produced by it.

An Obscure Abdominal Tumor.—DR. L. J. LADINSKI reported this case and presented the patient. She was a young married woman with a normal menstrual history. Six weeks before coming under observation, after having been constipated for several days, she developed malaise, headache, and a sense of fulness in the epigastric region. The following day she developed sharp pain in the splenic region. Under the local application of cold she improved, but the pain and vomiting recurred a week ago. Examination showed a very peculiar and indefinite tumor in the epigastric region. Repeated examinations of the urine showed the kidneys to be normal. The leucocyte count was 9,000. There had been a slight febrile action. Dr. Ladinski said that she had been seen by a number of physicians and various diagnoses had been made. Several members of the Section examined the woman, but were unwilling to make a diagnosis from such an examination alone.

A Study of the Degenerations and Complications of the Fibroid Tumors of the Uterus from the Standpoint of the Treatment of These Growths.—Dr. CHARLES P. NOBLE of Philadelphia read a paper with this title. He said that the classical teachings regarding fibroid tumors of the uterus still influenced a large part of the profession, and even gynecologists were still largely influenced by them in their writings and discussions. Long ago his own experience had taught him that these teachings were not trustworthy. Atless, the great pioneer in the treatment of fibroids, had detailed many of the dangers of these tumors, and his work was a strong argument against the classical teachings. Many years ago, Dr. Noble said, he had published a study of 218 cases, and this number had now reached 288. In estimating the risks encountered he first considered conditions which would necessarily prove fatal without operation. There were 88 of these complications enumerated, of which 42 were of the uterus or tumor and 48 of the appendages, making a total of 34 per cent. Considering other classes of cases, it was concluded that of the 288 cases probably 110 would have died, or 46 per cent. Of 100 cases of fibroids collected by Dr. Cullingworth of London, 52 presented degenerations. Pain was a prominent symptom in two-thirds of the necrotic cases. The ages of the patients varied between twenty-three and sixty-one, the majority being between thirty-five and forty-five. Certainly twenty-four of the cases would have died from the tumors themselves. Many of the complications were excluded by this author on the ground that they were independent conditions. Sloughing intrauterine polyps were likewise excluded on the ground that no one questioned the propriety of operating on such cases. If these cases had been included, the mortality would have been about that found in his own series of cases. Dr. C. C. Frederick of Buffalo had reported 125 cases of fibroids. Of this number twenty-three represented complications of the tumor and uterus, twenty-six of the appendages, and two did not involve the pelvic organs. It was thought that fifty-one of the cases would probably have proved fatal, and forty would certainly have done so. Remote systemic effects of these tumors should also be taken into account. Of 205 cases published by Martin, thirty-three would have certainly died if no operation had been done, because of the nature of the degenerative conditions present. The presumptive mortality without operation from degenerations confined to the uterus was, in Martin's cases, 16; in Noble's, 16; in Fredericks', 23, and in Cullingworth's, 24 per cent. Probably one-fourth of all the cases would result in chronic invalidism. The percentage of cases in which tumors had been found more or less accidentally was quite small. The speaker said that his own experience afforded no support for the view that fibroid tumors were prone to disappear after the menopause or in connection with pregnancy. Four of his patients having uterine fibroids were respectively seventeen, twenty-two, twenty-four, and twenty-six years of age. Twenty-one of the patients were between fifty and sixty years of age, and nine were between sixty and seventy years old. The oldest patient was sixty-seven years of age. The majority of them sought relief from the tumors at the very age when, according to the classical teachings, they should have been materially relieved by the influence of the menopause. H. A. Kelly said, in his textbook, that the great majority of myomatous uteri required no treatment whatever, and were often discovered only accidentally, and Montgomery taught, in his book, that the mere discovery of a myoma must not be considered as an indication for its removal, or even for treatment. These teachings, Dr. Noble said, were certainly contrary to the facts just presented by him. The presumptive mortality without operation from the degenerations and complications varied, as had been shown, from 16 to 24 per cent., and from complications outside of the uterus the presumptive mortality was slightly greater than from the tumor and uterus. It was a conservative statement that upward of one-third of women having fibroid tumors would die if not subjected to operation. The mortality of myomectomy and hysterectomy was between 2 and 10 per cent., depending upon the gravity of the cases, the operation and the environment. It, therefore, seemed a fair conclusion that resort to operation would save from 25 to 35 per cent. of mortality, and would perhaps affect a greater saving in the morbidity. He thought all fibroids should be removed unless the small size of the tumor, the advanced age of the patient, or her general health seemed to afford a justification for refraining from operative interference.

Dr. WILLIAM M. POLK opened the discussion. He said that he thought the reader of the paper had generalized too much and had not shown that certain of the conditions enumerated were directly dependent upon the degeneration in the uterus. For example, before one could accept carcinoma of any part of the uterus as being directly dependent upon fibroid of the uterus it must be shown that they were directly dependent one upon the other. Similarly, the enumeration of appendicitis, of ovarian tumor, and of dermoid cysts was not in order, these conditions all originating far more frequently independently of fibroids than with them. The author's position with regard to degenerations in the tumors themselves was less open to criticism, although there were many gynecologists who believed that the development of certain symptoms should be awaited before radical

operation was undertaken. It would be interesting to know what was the average size of the fibroid tumors before the various degenerative changes were noted, for this would bring up the question as to whether these changes ever occurred early in the disease, and whether early operation was demanded in order to anticipate these changes. As these changes were non-malignant in character, many would take the position that the operation need not be undertaken until symptoms of degeneration were present. He thought most gynecologists who found a fibroid tumor of moderate size giving rise to no symptoms would hesitate to advise a radical operation, and would rather trust to other measures of treatment which would appeal not only to them but to the good common sense of the patient. When, however, the tumor reached such a size as to lead one to fear the occurrence of degenerations there could be no question as to the propriety of operating.

Dr. Noble remarked here that he had not stated that fibroid tumors produced these conditions, and hence an element of confusion had been introduced into the discussion by the last speaker.

Dr. Polk replied that he understood that the whole purpose of the paper was to put the onus upon these complications, and that fibroid degeneration was made to stand in the breach and bear part of the penalty of the complications urged as reasons for extirpation.

Dr. W. Gill Wylie said that while deeply interested in the paper, he, too, was inclined to think that the generalizations were too sweeping. Personally he looked upon a fibroid as a new growth in which the degenerative processes were most apt to occur late in the life of the tumor. He did not believe that a fibroid should be removed, whether or not it was giving trouble, simply because it was a fibroid. He would go so far as to avoid, if possible, the removal of the fibroid if it were possible by temporizing to enable the woman to become pregnant and bear a child. Fibroids often existed without causing any trouble, and their presence was only discovered accidentally. When making such an accidental discovery, it was his rule, in the case particularly of a nervous woman, to withhold the information from her, though protecting himself by telling some member of the family. The presence of a uterine fibroid, by its change in the circulatory conditions, would ordinarily greatly aggravate inflammatory processes. He was disposed to think that a fibroid uterus was more susceptible than the normal uterus to carcinomatous degeneration. If a woman was over forty and the fibroid was giving rise to symptoms it was safer to remove it. If a fibroid should increase in size after the menopause it almost certainly indicated that degeneration was going on and that operation was demanded.

Dr. Egbert H. Grandin said that, to be fair to the author, one must carefully differentiate the classes of cases considered in the paper. Many of the cases of uterine fibroids came to him and were operated upon not because they had fibroids but because they had ovarian cystomata, pyosalpinx, dermoid cysts, or other conditions. Fibroids complicated by disease of the adnexa must be ruled out of this discussion, otherwise the discussion would be unending. Such a case would be operated upon not because of the condition of the fibroid but because of the other condition. His own belief was that these were mere coincidences, and were not directly dependent upon the presence of fibroids. If one could say, in a given case, that a fibroid was not going to undergo malignant degeneration, or the pedicle become twisted, then one would be willing to say that fibroids should not be operated upon unless they gave rise to symptoms. Unfortunately one could never say that, in a given case, a fibroid was not going to undergo malignant degeneration or become necrotic, giving rise to localized peritonitis. His experience had taught him that the practice in the future would be absolutely different from that laid down in the text-books already quoted. Given a fibroid of sufficient size to rise above the brim, and his advice would be to have it taken out. It was far simpler and safer to remove a fibroid when it was small and free from complications than to delay. If any of the complications mentioned did occur before operation, the latter would be made much more difficult and dangerous. These remarks had reference not to tiny fibroid nodules but to fibroid tumors which were palpable, and were not subperitoneal. He would all the more strongly advise removal if the patient were near the menopause, because at this time of life the tissues of the body were on the decline, and fibroids were most apt to degenerate. Between the ages of twenty and forty-five, if there were no excessive hemorrhages and he could keep the patient under observation, he might be willing to delay operation for a time.

Dr. J. Riddle Goffe indorsed the position taken by the last speaker, but was willing to go a little farther and say that *every* fibroid tumor discovered in a woman should be removed. Small fibroids occurring in young women should be removed in order to anticipate possible degenerative changes. In these cases the operation was extremely simple, it being practicable in many instances to remove them through the vagina. Young women should not be told they had a tumor, and that they should avoid marriage and pregnancy on this account, but should rather be informed that it was safest and best that the tumor be promptly extirpated.

Dr. Henry C. Coe said he believed a great many of the complications mentioned in the paper were not really dependent upon the fibroids, nor did he think the reader of the paper would take the very radical view presented by Dr. Goffe that all fibroids, even small nodules, should be promptly extirpated. As he understood it, Dr. Noble took the usual position, *i.e.* that fibroids of reasonable size giving rise to pain, pressure and hemorrhage, and of rapid growth, should be removed. If he were in error in this point it was because he had unfortunately heard only a portion of the paper. He was afraid Dr. Noble would not have a high opinion of the pathological knowledge of the members of the profession in New York City, for some loose statements had been made. Most of the cases of so-called carcinomatous degeneration of fibroids were really adenocarcinoma—a secondary and not a primary development. However, sarcomatous degeneration of fibroids did occur. The latest researches regarding the development of fibroids showed that they probably developed around arteries as a result of an endarteritis, and it had been shown in many cases that, in addition to the visible and palpable fibroids, numerous other fibroids, perhaps only the size of a millet seed, were scattered through the tissues. For this reason the enucleation of small growths had never appealed to him. Nothing had been said as get in the discussion regarding the locality of the tumor. He would operate upon a comparatively small tumor if it were situated in what he considered a bad locality. The mere presence of a small tumor in the anterior or posterior wall did not appeal to him from the surgical standpoint in the absence of symptoms. He had known a hysterectomy to be performed for a small submucous fibroid which could have been easily twisted off with a pair of forceps. He was of the opinion that a great many diseases of the adnexa were really due to the presence of fibroids.

Dr. H. J. Boldt said he still believed that merely because of the existence of a fibroid tumor an operation for its removal should not be done. It must be admitted that degenerative changes of the ovaries and tubes were undoubtedly caused by fibroids or fibromyomata, and ordinarily it was impossible to make a diagnosis of the presence of such changes. In the majority of instances, when marked changes were present outside of the uterus, such as pyosalpinx, there were symptoms of sufficient

severity to lead to surgical interference, and whether one operated because of the complications or because of the fibroids was of no importance. Perhaps the most important point made in the discussion was with regard to the location of the tumor. If the tumor were located in a region which would be likely to give rise to pressure symptoms, it should be promptly removed, because it was not at all unusual for the ureter to be pressed upon, causing pyonephrosis and other serious changes.

Dr. Mary N. Dixon Jones said that it had been stated in this discussion that fibroid tumors produced disease of the appendages, but she would take exception to this statement. It was the condition of the uterus which produced the fibroid tumors which gave rise to the disease of the appendages. In her microscopical studies of fibroid tumors she had been surprised to find how continually the tissues of fibroid tumors were reduced to inflammatory action. It was from medullary or "vital" material that fibroid tumors were produced. When this medullary condition existed in a fibroid tumor, cancer or other forms of degeneration might result. All the degenerations of fibroid tumors originated, in her opinion, in the medullary tissue. She believed that no fibroid tumor developed in a uterus unless the latter were already diseased, and that there never was a sound ovary in the presence of a fibroid of any considerable duration. In 1888 she had published the statement that no fibroid tumor of the uterus existed without disease of the appendages and of the cervix. This being the case, it was wrong to leave this diseased cervix, whether it was treated intra- or extraperitoneally.

Dr. Noble closed the discussion. He said that the paper treated of two general groups, the complicated and the uncomplicated ones. On tabulating the cases it became evident that so many cases were complicated that the risks from the complications demanded operation, and if operation were indicated for the complication there was no reason why it should not be done for the fibroid also. He had shown that from 16 to 24 per cent. of the women coming under observation presented conditions within the uterus which would prove fatal without operation. He had seen tumors of all sizes undergo degeneration, and, hence, the question of the size of the tumor seemed to him of but little importance in deciding upon surgical intervention. Dr. Grandin had made an exception in the case of subperitoneal fibroids, yet, personally, he had met with such fibroids which had shown degeneration or else twisting of the pedicle. If, as seemed to have been shown in the paper from the statistics of 600 cases, a woman with a fibroid stood 20 per cent. in danger of dying from the tumor without operation, and she could have it removed with almost no risk, it was evident that many women would be willing to submit to operation under these circumstances. The surprising thing about this subject to him was that many surgeons who would not hesitate to operate for various comparatively simple pelvic conditions object to the removal of the much more serious fibroid tumor. This he interpreted as showing the potent influence of traditions.

Tobacco Deafness.—Wyatt Wingrave reports seventeen cases of deafness which he considers to have been due to excessive tobacco smoking. He emphasizes the following points: (1) That they were all well-marked cases of nerve deafness occurring in heavy smokers. (2) That the loss of low-tones in 50 per cent. suggests an auditory equivalent for a recognized ocular lesion. (3) That there was definite scotoma in four cases and impaired sensation of vision in eight of them. (4) That the disease was symmetrical. (5) That 80 per cent. showed marked improvement on abstinence from tobacco, and this abstinence being supplemented by drug treatment, three were cured. But the habit was so strong and the will so weak that the forecast was not always encouraging.—*Medical Press and Circular.*

New Instruments.

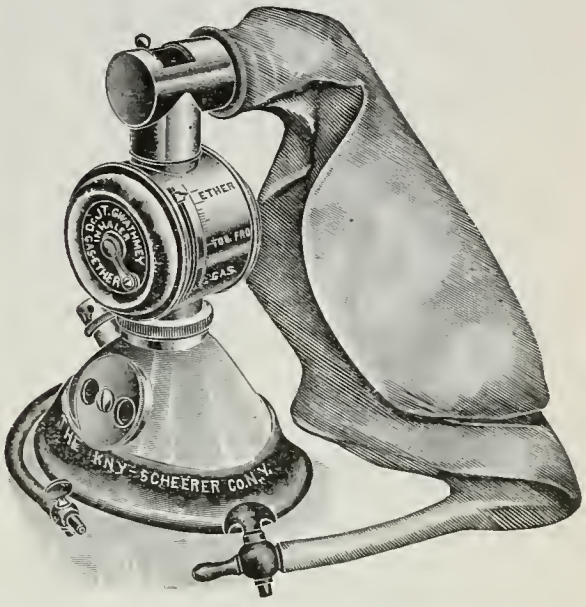
A NEW INHALER.

WITH SUGGESTIONS ON THE GAS-ETHER SEQUENCE.

By JAMES T. GWATHMEY, M.D.,
NEW YORK.
ANÆSTHETIST TO GOUVERNEUR, THE NEW YORK SKIN AND CANCER, AND CHARITY HOSPITALS.

It is really remarkable how very slow the medical profession is to take advantage of new methods and ideas that have been successfully employed by the most prominent surgeons for a number of years and in tens of thousands of cases.

The gas-ether method of inducing general anæsthesia was started by Dr. Clover in England over twenty-five years ago, and has been used very extensively in New York City for a number of years in private practice, but has been generally introduced into our hospitals only within the last year. The two things that possibly delayed the introduction of this method more than anything else have been the cost of the apparatus and its rather complicated mechanism.



Gwathmey Gas-ether Inhaler, complete; weight 26 oz.

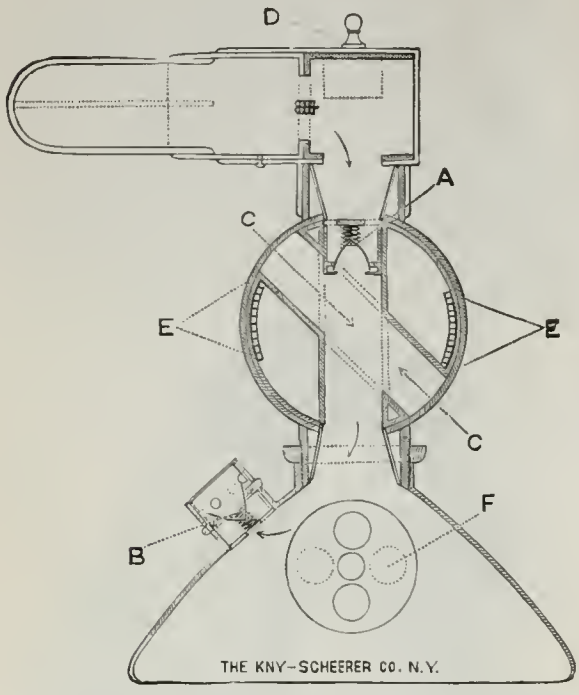
The objection to first giving gas and then changing to another inhaler for ether was that the patient would partially come from under the gas before getting completely under the ether, although this was an improvement over the old method of inducing narcosis with the open cone.

Clover finally perfected a combined gas-ether apparatus which was improved upon by Hewitt of England. Bennett's inhaler does not differ from the English apparatus in principle, but is a marked improvement in mechanical construction. It consists of a face-piece, two cylinders, one for the ether and one for the gas (the latter having an inspiratory and expiratory valve) and two bags, one for the gas, and the other for to-and-fro breathing, during the ether administration. The gas cylinder and bag are used between two and three minutes in the gas-ether sequence; they are then taken off and not used again during the entire anæsthetic.

The new inhaler, which is a modification of Bennett's (and perfected for me by the Kny-Scheerer Company, New York City), consists in doing away with this gas cylinder and bag, by placing one more tube in the ether cylinder with the inspiratory valve in it, and placing the expiratory valve on the face-piece. For all practical purposes this places the gas within the ether chamber. The same bag is used

for gas and ether. The weight and bulk is thus reduced nearly one-half. Bennett's complete apparatus weighing forty-six ounces, the new inhaler only twenty-six. Where space is in demand, as in army or navy use, or in an emergency kit, these are certainly no small considerations.

The valves, which are made of steel with a brass spring, are so arranged in tubes that they can easily



A. Inspiratory valve.
B. Expiratory valve.
C. C. Tube for to-and-fro breathing.
D. Tap for turning on and off the gas, admitting air when necessary; and also for pouring ether into chamber.
E. E. Openings to ether chamber.
F. Tap for admitting air through face-piece.

be taken out and replaced, if necessary; they are as light as a feather, giving perfect respiratory freedom. This allows the inhaler to be immersed in boiling water, or sterilized in the usual way, something that is impossible with the old inhaler with its rubber valves.

The tap on the gas-bag that is used for turning on and off the gas and admitting air when necessary, has been brought forward so that it answers the additional purpose of allowing the ether to be poured directly into the ether chamber, which is quite a convenience during the first part of the anæsthetic, when the patient is coming out of the gas, and is not thoroughly under the ether.

The inhaler can be used for giving ether alone or gas alone, or the gas-ether sequence or the combined method of giving gas and ether at the same time.

The object of the gas-ether sequence is to avoid the first and second stages of ether narcosis, with its preliminary excitement, struggling, coughing, holding the breath swallowing, and all other disagreeable and disgusting things that were formerly connected with this stage of etherization, and to enter immediately into the third stage or surgical anæsthesia. The patient is thus enabled to take advantage of the most universally used and safest general anæsthetic in the most agreeable manner possible, and with the least physical and nervous strain. It is the exception for the patient to show any excitement whatever, and deep anæsthesia is generally reached in about three minutes. With the open cone the average time required to produce surgical narcosis was about ten minutes, and with this method patients dreaded the anæsthetic in some instances even more than the operation.

Drachms of ether are used with the inhaler, where ounces were used with the open cone, consequently the patient is not so saturated with the drug as formerly, and thus escapes many of the after-effects of ether. The nausea and vomiting are in all cases materially lessened by turning the patient's head to one side during the administration (allowing the mucus and saliva to drain out), avoiding moving or jolting the patient for at least thirty minutes, and turning the patient on one side immediately after the operation whenever possible. The olfactory nerve is largely responsible for this disagreeable feature of ether narcosis. It is therefore advisable to remove at once all towels, etc., that may contain the smell of ether and substitute some cologne (if not too sweet) or other odor that may be agreeable to the patient.

At the suggestion of Dr. Monroe of the House Staff of Gouverneur Hospital, I have lately replaced the gauze used for packing the ether chamber with sponges, as they throw less strain upon the lungs in maintaining the same degree of anæsthesia, the diaphoresis is less and the exhaustion is not so marked following a long anæsthetic. For this reason the ether chamber is made to hold sponges, although gauze can be used. The face-piece has also been considerably altered and fits more comfortably and securely.

The mechanism has been simplified to such an extent that the technique can be easily acquired by any surgeon or hospital interne, and the cost so materially reduced that any surgeon can now afford to have this apparatus added to his armamentarium.

124 East Sixteenth Street.

AN ASEPTIC COTTON-HOLDER.

Designed by C. Y. HOGSETT, M.D.,
Dallas, Tex.

The construction of this holder, intended for use in the treatment of the eye, ear, nose, and throat, is easily understood from the accompanying cut. It consists of a leaded metallic base, upon which rests a double metallic cylinder four inches in length and two and one-half inches in diameter. Through the center of this passes a square steel rod, at one end of which there is a tap, at the other a small crank for turning the rod. The outer cylinder is attached to

the metallic base below, is open at both ends, and at its upper part has an opening one and three-fourths of an inch in width, extending through the entire length. The inner cylinder fits within the outer, is closed at both ends, and has an opening corresponding to that in the outer cylinder. Near the center of one side of the opening there is a small metallic knob by which the inner cylinder can be moved within the outer, thereby completely closing or opening both cylinders. The receptacle for the cotton holds the amount that comes in the smallest-sized packages. By placing one end of the roll of cotton into the opening of the receptacle and then turning the crank the cotton will be wound into a roll on the central

rod, just the same as a bandage is wound on a bandage roller.

The holder possesses certain advantages. It is simple and compact, and is easy to fill. There is no piece to become detached, misplaced or lost, thereby leaving the cotton exposed to contamination from dust and other impurities. It is easily opened and closed and when closed is dust proof. The cotton is wound in the direction of the long fibers and does not become matted or twisted. Pieces of cotton can be pinched off the roll without any resistance, and, as it comes off soft and fluffy, it can easily be wrapped firmly and smoothly on an applicator. If necessary, it can easily be sterilized. The cotton-holder is made by E. B. Meyrowitz of New York City.

THE THERMOMETER SHIELD.

By HARRY VAUGHAN, Ph.G., M.D.,
MORRISTOWN, N. J.

There have been many devices offered to the medical profession for sterilizing the clinical thermometer, but none of them is quite satisfactory, and all demand some labor on the part of the physician, and the expenditure of a little time, which he is not always able to give, at the bedside. A consideration of these facts has led me to suggest the use of a shield of very thin rubber tissue, which can be slipped over the bulb of the thermometer and extends far enough up the stem to protect it from contamination. The shield is so exceedingly thin that it will not in the least interfere with perfect action of the thermometer. The shield is intended to be used once only and then to be destroyed. This avoids all suggestion of uncleanliness, and does away with all possibility of carrying infection from one patient to another. The shields are very small, about the size of a two-grain capsule, and are packed in a small aluminum case for convenience in carrying. They are made by the Arrowsmith Company of Newark, N. J.

A HÆMOGLOBIN SCALE.

We have received from Mr. Edward Pennock of Philadelphia the hæmoglobin scale, devised by T. W. Tallqvist of Helsingfors. It is simply a book of detachable squares of filter paper with a colored scale in the back. In making a test a square of paper is torn out and applied to the specimen of blood in such a way as to absorb it slowly. When completely wet with the blood it is pressed against a piece of blotting paper to remove the superfluity of fluid, and as soon as the stain has lost its humid gloss, it is compared with the scale. If care is taken to make the comparison in daylight the percentage of hæmoglobin can be quite accurately determined.

An Experimental Study of the Function of the Pituitary Body.—Domenico Pirrone concludes from his observations: (1) That not all the symptoms following hypophysiectomy are referable to the suppression of the functions os the pituitary body. (2) The results of the suppression of its functions are disturbances of mobility, great depression, rapid emaciation, cachexia, and death. (3) The symptoms due to trauma are referable to the vascular and respiratory systems and the temperature. (4) Total ablation of the pituitary body does not alter the chemical composition of the urine. (5) Although the exact functional mechanism of this gland is not as yet well understood, it is evident that this organ is of the greatest importance to the economy. Although a partial lesion is compatible with existence, its total removal leads irrevocably to death.—*La Riforma Medica*, February 25, 1903.

Books Received.

While the Medical Record *is pleased to receive all new publications which may be sent to it, and an acknowledgment will be promptly made of their receipt under this heading, it must be with the distinct understanding that its necessities are such that it cannot be considered under obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

Materia Medica for Nurses. By John E. Grodd, Ph.G. 12mo, 169 pages. Second Edition. P. Blakiston's Son & Co., Philadelphia. Price, $1.25.

Hygiene and Public Health. By Louis Parkes, M.D. 12mo, 763 pages. Illustrated. P. Blakiston's Son & Co., Philadelphia. Price, $3.00 net.

The Pathogenesis and Therapy of Eclampsia.—Hengge, after a complete review of our present knowledge as to the nature of this affection, comes to the conclusion that the bacterial or bacteriotoxic theory is still without adequate proof. So far the observations on the toxicity of blood and urine, according to Bouchard's methods (injections, experiments, specific gravity, molecular concentration, electrolysis), have also failed to permit of satisfactory deductions. Investigations on the freezing point of blood and urine show that there exists a condition of insufficient molecular diuresis in three-fourths of all pregnant women. In eclampsia, at the beginning of the attacks, there is a wholly insufficient molecular concentration of the urine, and this condition may exist even with total absence of albumin. These observations correspond with those made in other renal disorders. The relations of maternal and fœtal metabolism are very intimate, but there appears to be a certain degree of exception for soluble albumin combinations. The biochemical theory of Veit seems to explain many of the observed facts, such as the transitory albuminuria of pregnancy. From the standpoint of treatment, prophylaxis is of the highest importance and comprises systematic freezing-point determinations as well as the testing for albumin. Our therapeutic measures should, above all, be free from risk; therefore the narcotics should be carefully used, and the newer remedies, such as veratrum, lumbar anæsthesia, and iodothyrin should be made subjects of further clinical study. The induction of labor is best effected by the use of the metreurynter or Bossi's dilator. In multiparæ the membranes may be ruptured, but Dührssen's incisions are not advisable.—*Volkmann's klinische Vorträge.*

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending April 4, 1903:

Typhoid fever	36	4
Cerebrospinal meningitis	..	..

Mercurial Reaction of the Oral Mucous Membrane in Syphilitics.—Eugene Baroch reports five cases of late secondary syphilis in which the initial application of a large amount of mercurial ointment caused, within eighteen to twenty-four hours, the appearance, upon the tongue and oral mucous membrane, of large red spots, which were somewhat serpiginous in appearance and were painful. The spots disappeared within a few hours and did not return, although the inunctions of mercury were continued. If such applications were discontinued for a long time the reaction reappeared following a new initial inunction. No cutaneous reaction, as has been recently described by Herxheimer and Krause as occurring in early secondary syphilis, was observed. The cause of these mercurial reactions in syphilitics is somewhat obscure, but is probably to be sought in the chemical effects produced by the union between the mercury and the syphilitic virus. In those cases in which such a chemical reaction is sufficiently intense the reaction appears. Its non-appearance with continued inunctions of mercury is explained by the fact that the initial dose combines with the larger part of the syphilitic virus present in the location where the inunction is employed, hence the chemical reaction elicited by subsequent inunctions is not sufficient to produce the cutaneous reaction. The surplus of mercury left over after all the syphilitic virus is "anchored" would probably unite with the red blood-cells, in certain numbers destroying them, and thus prevent the cutaneous reaction from being seen even if it was present. However this may be, the reaction possesses marked diagnostic importance. Its appearance means a positive diagnosis of syphilis. Its absence, however, does not negative the presence of this disease, since in many syphilitics the chemical reaction above referred to is not sufficiently intense for the cutaneous reaction to be seen. The appearance, in late secondary syphilis, of the reaction only upon the tongue and oral mucous membranes is probably to be sought in the location of the most marked syphilitic lesions present in this class of cases. Oral lesions are always a prominent feature in such cases and persist long after the other cutaneous manifestations have vanished. In accordance with the above theory, the reaction would appear wherever the syphilitic virus was in largest amount, provided the mercury was not united to the virus while in transit through the body from its point of inunction to such locations. In late secondary syphilis the oral mucous membranes are undoubtedly locations in which the virus is markedly accumulated. Hence in these cases the reaction appears exclusively in this region.—*Allgemeine medicinische Central-Zeitung.*

Possibilities of the Normal Salt-solution.—L. C. Davis says that the human body may be compared to an acute circumscribed abscess. Before it is possible for the regenerative powers of the tissues to restore the normal condition of the part, it is necessary to open the abscess and drain it of the poison, causing the pathological process, so it is with the entire body, it must be drained of a certain amount of the toxic blood and replaced by an agent that will assist regeneration; and in the normal salt-solution we have that agent, to be used in coöperation with other effective means we now have at our command.—*Medical Herald.*

Health Report.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, U. S. Marine Hospital Service, during the week ending April 4, 1903:

A REPORT OF FINAL RESULTS IN TWO CASES OF POLYARTHRITIS IN CHILDREN OF THE TYPE FIRST DESCRIBED BY STILL, TOGETHER WITH REMARKS ON RHEUMATOID ARTHRITIS.*

By ROYAL WHITMAN, M.D.,
NEW YORK.

In 1897 G. F. Still of London published an account of a peculiar form of chronic-joint disease occurring in children.† The disease was defined as a chronic progressive enlargement of the joints associated with general enlargement of the glands and of the spleen. The onset of the affection was usually insidious, although it might be acute and accompanied with fever. The swelling of the joints was smooth and fusiform, not attended by redness or heat except in acute cases. The disease was progressive, and there was enlargement of the lymphatic glands and of the spleen. The lymphatic enlargement was most marked in the glands communicating directly with the joints, and its degree varied with the character of the local process.

The joints most often involved were the knees, wrists, and the spine. There was usually flexion deformity of the wrists, and in some instances lateral deviation of the hand toward the ulnar side. The smaller joints of the hands and feet were not not affected.

There were early and marked wasting of the muscles, waxy pallor, anæmia, and arrest of development. The disease progressed for a time and then became stationary. Improvement was possible Three post-mortem examinations showed the joint lesions to consist essentially of thickening of the capsule and of the connective tissue just outside it, and thickening and vascularization of the synovial membrane. The cartilage was normal, except in one instance, in which pitting beneath a fold of synovial tissue was noted.

Still had personally observed nineteen cases and had notes of three others, yet he confined his statistics to twelve cases. In ten of these the disease began at or before the sixth year, and in eight during the first three years of life.

This type of disease must be uncommon in this country, and I take this opportunity to report two cases which should be of special interest because they present certain variations from those reported by Still.‡

Case 1.—A boy twelve years of age was admitted to the Hospital for Ruptured and Crippled on October 23, 1899, having been under observation in the Out-door Department for several months. The family and personal history is not of special interest. He had first complained of discomfort in the right knee during the previous July. This became more noticeable, and soon stiffness and swelling appeared. Because of the evident persistence and progressive character of the local symptoms a diagnosis of tuberculous disease was made. On this diagnosis he was treated in the wards, and was discharged in the following January, wearing a protective brace on the right leg. During his stay in the hospital it was recorded that slight stiffness and swelling had been observed in the left knee and in the right elbow. After the patient's discharge he attended public school until the end of the term in July, when he was again admitted to the wards because of the extension of the disease. From this time he was under observation until his death on January 23, 1903, about three and a half years from the onset of the symptoms.

It was not until July, 1901, or about a year after his second admission, that my attention was first attracted to the patient. He was at this time bedridden, lying constantly on his back with the legs extended, an attitude that had been assured by the almost constant use of plaster bandages, which were applied also from time to time to fix the wrists and elbows when the pain on motion was extreme.

All the larger joints of the body were now involved, only the sternoclavicular joints, those of the fingers and toes, the lower jaw and the spine being free from disease.

Taking a knee-joint as a typical example of advanced disease it might be described as a fusiform enlargement accompanied by atrophy of the muscles so extreme as to exaggerate greatly the size of the affected joint. The tissues covering it were thickened, infiltrated, and sensitive to pressure. Motion was greatly restricted and very painful. In the joints more recently involved, especially the shoulders, there was well-marked synovial effusion, and the pain on motion was slight. The disease was well advanced in both wrist-joints and on the right side, in spite of the almost constant use of a plaster support there was evident anterior subluxation of the carpus, so that the lower extremity of the ulnar projected on the dorsal surface. The general emaciation was extreme and the pallor was marked. The abdomen was prominent and resistant, and there was evident enlargement of the liver and apparently of the spleen also. In the groins and in the axillæ were numerous enlarged lymphatic glands, visible as well as palpable, not sensitive to pressure or adherent to the tissues. At times there was slight redness, and increase of local heat in the affected joints.

On July 2, 1901, I opened the left knee-joint by a long incision over its internal aspect. The capsule was thickened and apparently adherent to the subcutaneous tissues. Its interior was lined with dark red soft granulation tissue which had replaced the synovial membrane. This tissue surrounded the marginal cartilaginous surfaces of the component bones, creeping over them here and there in a pannus-like growth, which eroded and destroyed the surface on which it rested. Elsewhere the

†Medico-chirurgical Society Transactions, 1897.

‡The treatment of these cases was shared by my colleagues at the Hospital for Ruptured and Crippled, Drs. Gibney and Townsend

cartilage was normal, the bone was apparently not involved. There was no formation of ecchondroses or osteophites. The fluid within the joint was slightly increased in quantity, and it was redder and thinner than normal synovia. Passive motion in the joint was limited to about 40°, primarily by the thickened and contracted capsule. The more prominent granulations having been scraped or rubbed away, the interior of the joint was swabbed with pure carbolic acid, this was neutralized by alcohol. Afterward the joint was cleansed with salt-solution and the wound was closed with sutures in layers. It was thought that the discomfort was lessened by the operation, but no other effect was noted.

On August 27 the right knee-joint was opened and treated in the same manner. The appearances were precisely the same as have been described.

In September the right wrist, in which the swelling had increased, was opened by a long dorsal incision. The extremity of the ulnar was found to be separated from its attachments and in great part denuded of cartilage. The cartilage of the radius presented a deep erosion, running from before backward. The first row of carpal bones were imbedded in a mass of succulent mucoid granulation tissue, from which they were easily removed, their surfaces presenting the slight characteristic erosions. The articular surfaces of the radius and ulnar were removed, and the hand was then replaced in proper position. It was impossible to close the wound, as the skin was so thin and ill-nourished that the sutures would not hold.

This fragility of the skin was increased, apparently, by a scaly eruption, which at first appeared beneath the plaster bandages, not only at the wrist but at the knees, and eventually extending to other parts. Its nature was apparently obscure to the consulting Dermatologists. It was very resistant to treatment, and it finally received the name of lichen scrophulosum. The wound of the wrist closed slowly by granulation. (Fig. 1.)

The after history is simply of progression of the disease. Eventually every joint, except the jaw and the spine, was involved, the fingers of the right hand and the toes of both feet being greatly enlarged by effusion into the phalangeal joints. Curiously, and apparently as a result of the operation, the finger-joints of the right hand became fixed in a claw-like position (Fig. 2), without effusion or enlargement, while the joints and tissues of the left hand became greatly enlarged, even the periosteum of the shafts of the phalanges becoming infiltrated, as shown by an *x*-ray picture. (Fig. 3.) The abdomen became more prominent and the color and outline of the liver could be plainly seen through the thin and transparent skin.

The Pathologist failed to find tubercle bacilli in the skin at the diseased points. The examination of one of the glands showed simply hyperplasia. The tissues from the knee and other joints was reported as inflammatory material of an undetermined nature. Fluid was removed from the joints for bacteriological examination, but with apparently negative results, as I find no report in the record. The repeated examinations of the blood showed only secondary anæmia with an increase of eosinophiles. The immediate cause of death was undetermined.

The report of the autopsy may be summarized as follows: The liver was enlarged to about three times its normal size, extending from the fourth rib to the brim of the pelvis, and presented marked amyloid degeneration. The spleen was correspondingly enlarged, rather soft, plum colored, with here and there areas of amyloid degeneration. The kidneys were about one-third larger than normal, soft and nodular, showing decided acute parenchymatous nephritis and amyloid degeneration. The pancreas was enlarged and firm in consistency. The adrenal glands were free from disease. All the mesenteric glands were enlarged, yellowish white, firm, showing amyloid degeneration. The thoracic organs were practically free from disease.

Fig. 1, Case 1.—A photograph, taken in the third year of the disease, about six months before death, showing the appearance of the affected joints and the enlargement of the abdomen.

Several of the joints were removed for inspection. The local appearances were similar to those already described. The cartilage of the head of the right humerus presented several deep "worm-eaten" perforations. At the right elbow there was even more extensive erosions of the cartilage than in the other joints examined. On section of the bones of the knee-joint one was struck by the uniform dark red color of the spongy substance; its structure was, however, firm and regular. The cortical substance of the bones was extremely thin, as was the articular cartilage.

Case 2.—The patient, a boy five years of age, was admitted to the hospital in April, 1900. The family and personal history presents nothing of particular interest. About eight months before admission he had begun to complain of pain and stiffness at the right knee-joint. He was brought to the hospital in arms, and it was said that he was unable to sleep because of pain.

On examination the right leg was found to be flexed and adducted, and there was limited motion and muscular spasm about the hip-joint, as well as at the knee. He was placed in bed with traction, and finally the deformity was corrected under anæsthesia. For a time a double spica-plaster bandage was worn, which was afterward replaced

by a double Thomas hip-brace. Six months later it was noted that there was swelling at the wrists and ankles, and, in December, of the elbows, also. In July, 1901 (Fig. 4), when my attention was first attracted to the patient, the similarity of the symptoms to those of the first patient was striking. There was general enlargement of all the joints, of the character already described. The average range of motion permitted by the thickened capsules and muscular spasm was about 40°. There was persistent flexion at the elbows and at the wrists. The use of apparatus had prevented deformity of the lower extremities. The joints of the fingers and toes (Fig. 5) were free from disease, as was the spine. The abdomen was enlarged, and the liver and spleen were apparently hypertrophied, although not to the degree noted in the first case. The lymphatic enlargement was, however, more noticeable. The weight of the patient was twenty-three pounds.

FIG. 2, CASE 1.—Shows the contrast between the two hands; also the disease of the skin

On July 30, 1901, I opened the left knee-joint. The appearances were exactly like those in the other case, except that beneath the patella sprouted upward a fatty mucoid-like growth, deep red in color, and about the size of the patient s little finger. This was removed, and the interior of the joint was treated with pure carbolic acid in the manner described. A lymph gland was removed for examination; it showed simple hyperplasia.

During the autumn there was sufficient improvement to enable the patient to be about the ward on a wheeled chair. From the latter part of November until the middle of January, he was treated by daily exposure of the naked body to the heat and light supplied by numerous electric lights beneath a tent-like covering. He continued to improve after the cessation of treatment, and his cure was completed, apparently, by an attack of scarlatina, which necessitated his removal to the Willard Parker Hospital in April, 1902. At the present time he is fat, strong, and active, and presents no trace of disease.

From my observations on the course of the disease, and from the local conditions exposed at operation I infer that the sequence of events in this class of cases is somewhat as follows:

The process begins primarily in the synovial membrane, probably as a congestion accompanied by effusion of moderate degree. As the disease progresses and as the deeper parts of the capsule become infiltrated the original stiffness and discomfort increase and the affected joint becomes sensitive to motion and to pressure. The muscular atrophy that always attends joint disease is exaggerated doubtless by the multiplicity of the joints involved. The interior of the capsule becomes lined eventually with what corresponds to granulation tissue; this encroaches upon the margins of the articular cartilages, which it slowly erodes, and doubtless the adjoining marginal bone on which it rests as well. The capsule thickens and becomes adherent to the overlying tissues; the cavity of the joint is lessened and it may be finally obliterated. The final result should be limited motion or fibrous anchylosis in an attitude of deformity with attendant atrophy of the substance of the bones, corresponding in degree doubtless to that of the soft parts.

There can be no doubt but that these cases are examples of the disease described by Still, yet they present certain variations of the type. In one case there was complete recovery, of which Still records no instance. He mentions enlargement of the spleen only, yet in both these cases the liver was enlarged, in one case extremely so, ending finally in amyloid degeneration. In Still's cases the joints of the fingers and toes were exempt, while the spine was involved at an early period of the disease. In one of these cases all the small joints were diseased, while in neither was the spine affected. Still mentions slight pitting of the cartilage in one case that came to autopsy, as if this were an unusual occurrence, while my examination shows that such erosion is an inevitable outcome of advancing disease.

It is of interest to consider the relation of these cases to those described by Schüller as polyarthritis chronica villosa (*Berliner klinische Wochenschrift*,

FIG. 3, CASE 1.—An *x*-ray picture of the left hand.

January 27, 1900) and to the atrophic form of arthritis deformans. The term atrophic signifies that form of chronic polyarthritis not accompanied by marginal outgrowths of bone and cartilage, and for convenience, following the suggestion of Goldthwait, I shall class this variety of disease as rheumatoid arthritis and consider it as distinct from osteoarthritis or the hypertrophic form of arthritis deformans.

In the ordinary form of rheumatoid arthritis the effusion is less marked than in the cases described, and finger joints, particularly the first interphalangeal articulations, are usually affected; but in childhood at all events the disease may first appear and remain for a time in one of the larger joints, the symptoms simulating tuberculous disease so closely that diagnosis is impossible until the extension of the disease to other joints shows its true character. In some instances the fingers remain free from disease. The spine may or may not be involved.

In this class of cases the local disease appears to correspond closely with that already described, beginning in the soft parts and involving the cartilage and the bone secondarily. In a typical case

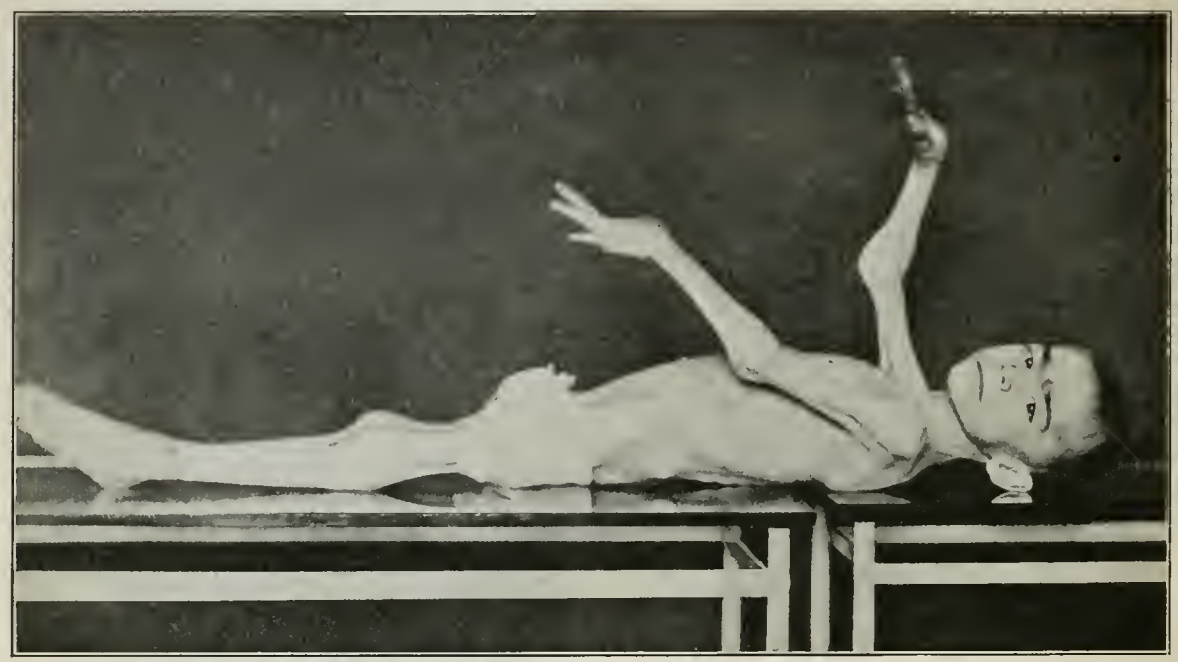

Fig. 4, Case 2.—A photograph, taken in the second year of the disease, about one year before recovery, showing the enlargement of the joints and the extreme emaciation.

of this character in which I removed the astragalus recently with the aim of restoring motion and relieving pain, I found complete anchylosis at the ankle-joint, the pain being due evidently not to joint motion but to recurrent sensitiveness in the thickened and infiltrated tissues covering it.

I may note in this connection that although it is often stated that arthritis deformans is uncommon in childhood it is certainly not particularly so in orthopedic practice. In my experience cases of this class are usually of the atrophic type (rheumatoid arthritis), yet the anatomical descriptions that one finds in the textbooks are usually of a disease accompanied by central atrophy of the cartilage, thickening at the periphery distortion of the joint surfaces and the like, a description that applies to the hypertrophic form (osteoarthritis).

Although from the clinical standpoint a case of rheumatoid arthritis in childhood is absolutely distinct from a typical case of osteoarthritis, such for example as the malum coxæ senile, yet there are many cases that it would be difficult to classify. For instance, the irregular enlargement of the bases of the terminal phalanges of the fingers with erosion of the cartilage may be classed as typical examples of the osteoarthritic process, yet these Heberden's nodes may be present in cases of rheumatoid arthritis, or they may be, and often are, present when the other joints are free from disease. So also the spine may become anchylosed in either form of disease, always apparently by a form of ossifying periostitis. The same process may be induced by gonorrhœal or other infection, and it may exist independently of any joint involvement and without evident cause (spondylitis deformans).

In cases of rheumatoid arthritis, as in the two cases described, the appearances suggest the effect of a continuous feeble irritation within the joint and a correspondingly feeble reaction. From this point of view one may explain the importance of supervision that would assure the individual from the depressing influences of over-exposure and over-work, and support his vitality by proper nourishment. And the value of local treatment to stimulate the circulation, such as massage, heat, light, the *x*-ray, and static electricity, both generally and locally. The advantage of the prevention and correction of deformity and of local support to relieve painful motion during the exacerbations of the disease are, of course, apparent.

As has been mentioned, one of these patients improved under daily exposure to heat and light, but apparently he improved even more rapidly after the attack of scarlatina. This favorable influence of contagious disease is often seen in ordinary rheumatoid arthritis of childhood, although in my experience the improvement is usually temporary. Whether it is an example of direct germ antagonism or, as seems more probable, it is simply the effect of a change in the general and local nutrition, is undetermined. This suggested to me the employment of Coley's fluid for the purpose of exciting the same reaction, and it was used in the case of the older patient, but only a short time before his death, when beneficial effect was hardly possible. No local change in the diseased joints was observed.

As far as the effect of operation is concerned, it may be stated that certainly no harm resulted and I should be inclined to repeat the procedure, especially if but one or two of the larger joints were involved, with the aim of exciting a local reaction that might stimulate the reparative process.

One can hardly conclude without mentioning the vexed question of etiology. As has been stated, the local appearances were indicative of feeble irritation and feeble reaction, but this does not imply

Fig. 5, Case 2.—Shows the swelling of the wrists, the finger-joints being unaffected.

that this form of disease, or rheumatoid arthritis in general, is not a painful affection. When the disease is confined to a single joint, which is therefore usually subjected to the strain of activity, it may be as painful as the ordinary form of tuberculous disease, but when the patient is disabled and has become habituated to discomfort, pain is usually less prominent as a symptom.

If rheumatoid arthritis is to be considered as of infectious origin, its distinction from ordinary forms of infection, whether local or general, is certainly marked. In the forms of infectious joint disease, which are commonly seen of the multiple type, such as may follow pneumonia, scarlet fever, and the like, the stage of invasion and progression is of comparatively short duration, and it is followed by repair. It is true that in gonorrhœa there may be successive involvement of joints at intervals, but even in such instances, the period of invasion is short compared with that of rheumatoid arthritis, which may extend over indefinite years. To account for this course one must presuppose a focus of infection within the body which is constantly active. Secondary osteoarthropathy is the only instance with which I am familiar in which such a source of infection seems to be fairly evident.

I find that disease of the nervous system still occupies a prominent place in the etiology as given in the textbooks, an hypothesis which is even more unsatisfactory than the last, because there is no known disease of the nervous system that is ever followed by joint disease such as has been described. It is true that disorganization of one or two of the joints may complicate locomotor ataxia and, in rare instances, certain other nervous diseases, and that the local conditions have been described as a caricature of osteoarthritis; but such joints neither in physical characteristics nor distribution, nor symptoms, resemble those under consideration. Even in the ordinary form of rheumatoid arthritis in older subjects, the symptoms ascribed to disease of the peripheral nerves, such as atrophy, change of nutrition, disordered sensation, and the like, accompany rather than precede the joint manifestations, and they differ in no particular from the symptoms caused by joint disease due to local infection.

Disordered metabolism as a cause of chronic joint disease, whether acting directly or indirectly through the trophic centers, is a theory so indefinite that it is hardly open to criticism, and it is of service therefore as an indication of our ignorance of the subject. This ignorance can be enlightened only by a better understanding of the various types of diseases that are now included under the term of arthritis deformans. To this end one should always make a primary distinction between the atrophic form of chronic polyarthritis and the hypertrophic form. The first is the common form in early life. The second is less common, less disabling, less general in its distribution, and is, relatively, infrequent in patients under middle age.

It can hardly be claimed that the cases reported as final results throw any particular light upon the etiology of this form of disease. To one seeing only the autopsy, the hypertrophied and degenerated internal organs, the general enlargement of the glands, the extreme emaciation and the abnormal color of the divided bones, would certainly have suggested some general disease to which the joint lesion was simply incidental; but the history shows that the disease of the joints was for a time at least the most important indication for treatment.

The recovery of the second patient from a condition as desperate as that shown in the photographs makes an interesting addition to the history of Still's disease, if it is to be considered as a distinct affection.

126 West Fifty-ninth Street.

The Treatment of the Autointoxications of Pregnancy by Thyroid Extract; the Anticipation of Impending Eclampsia.—H. Oliphant Nicholson reports the case of a woman on whom the thyroid treatment was tried during pregnancy, as her first confinement had been complicated by eclampsia. Labor was practically painless and a living infant was born, and the thyroid treatment was discontinued. On the sixth day after a severe eclamptic fit occurred, thyroid was administered in large doses, and recovery ensued. On the nineteenth day death occurred suddenly from symptoms suggestive of cardiac thrombosis. The authors report in detail the effect of the thyroid treatment on the elimination and composition of the urine. The most valuable action was a notable increase in the elimination of urea, because it is well recognized that the urea excretion fluctuates *pari passu* with the elimination of the toxic substances. Thyroid extract seems to possess a definite action in favoring the elimination of the solid constituents of the urine, which, for some reason, are locked up in the tissues, and in this way certain poisonous products of metabolism are also passed out of the body. These substances must be regarded as the cause of the autointoxication and subsequent convulsions. Even in cases of normal pregnancy, where slight symptoms of autointoxication may possibly develop under an excess of proteid food, it would seem rational to administer thyroid extract as a form of prophylactic treatment in order to anticipate more serious trouble. —*The Scottish Medical and Surgical Journal*, March, 1903.

"EYE-STRAIN" IN YOUTH AND ITS MODERN TREATMENT.

By AMBROSE L. RANNEY, A.M., M.D.,
NEW YORK.

Difficulties in using the eyes, accompanied by pain, and often by other symptoms of distress, may affect both the young and the old.

Thousands of children are taken from school yearly on the advice of some intelligent physician because of serious impairment of the general health. Yet thousands more are unfortunately compelled to use their eyes in both study and other vocations long after the evil consequences of "eye-strain" become manifest to a marked degree.

Sufferers from eye-strain are often fortunately restored to perfect physical health and are relieved of all eye symptoms rapidly by properly fitted glasses. The proportion that is so relieved is unquestionably enormous.

It is no longer infrequent, especially in large cities

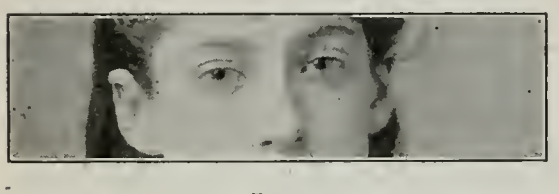

Fig. 1.

Fig. 1.—*A typical tilt of the head from "hyperphoria."* Notice that the right-hand side is much higher than the left. The high eye is very apparent.

and among the offspring of educated parents, to see glasses worn constantly by children of tender years.

Parents have begun to realize at last that it is wiser to endure what naturally seems to them to be a disfigurement to a child than to allow the general health of the child to gradually become undermined by defective eyes and to have its education seriously interfered with on account of uncorrected eye-strain. They have learned what some medical men seem to refuse to learn, viz., that a child or adult may suffer in many ways in consequence of eye-strain and still complain of no eye symptoms; and that headache, weak digestion, nervousness, and other evidences of physical debility may be but "flags of warning" that nature hangs out to tell that a leakage of nervous force exists from unsuspected eye-strain. Too much stress cannot be laid upon the fact that severe types of eye-strain often exist in connection with eyes that have the most acute vision and that cause no apparent discomfort.

Because a child can see unusually well, because the eyes cause no discomfort, because the eyes do not twitch or get inflamed, because the eyes will stand more than the average amount of work, it is natural, but still illogical, to argue that there is no basis to suspect that eye-strain may exist.

In spite of such statements on the part of a child

Fig. 2.

Fig. 2.—*The high eye in this face is easily detected.* Notice the tilt of the head from "hyperphoria."

or adult, clinical records show that the results of an investigation of eyes that are apparently perfect often shed much light on the causation of obscure nervous symptoms far removed from the exciting cause, viz., eye-strain.

Personally, I suffered for thirty years from terrific headaches, frequent attacks of uncontrollable vomiting, and extreme nervous debility at times. These attacks began in full severity when I was but four years of age. They persisted, in spite of all drugs, until I found, by accident, that eye-strain was the exciting cause. Yet, during all these years of acute suffering, that terminated finally in a complete physical collapse when I was still a young man, I

Fig. 3.

Fig. 3.—*Expression of a patient with extreme esophoria closely bordering upon convergent "squint" but maintaining binocular vision.* Notice the intense expression of the eye in this young face.

had never had an eye symptom of which I was conscious and I had remarkably acute vision. The correction of my own eye defects restored me, as if by magic, to health and a capacity for labor that I had never before known. My poor abused liver, that had been stirred up by drugs for years to abort the paroxysms of pain, must bless the day that revealed the actual cause; and the use of tobacco, to which many eminent men had attributed my sufferings, is still my solace and delight. At different times in my life, my headaches had been diagnosed as due to "nicotine poisoning of the retina," cerebral congestion, fermentation of food, insufficient bile secretion, and many other speculative conditions, while the actual cause was discovered by myself almost by accident, and my life's work became an outgrowth of my recovery and restoration to health. Had I lived as a child in the age of present enlightenment, I would have been spared weekly attacks of pain that frequently made suicide attractive to me, that robbed me of an ability to fill my engagements for nearly ten years (in the aggregate) out of thirty, that made me prematurely gray, and that in the end brought me to a condition of despair, without evidence of any organic disease to account for my collapse.

Three of the leading oculists of my own city had been asked by me to examine my eyes within one week. They had all used only the ophthalmoscope and test-cards. They had all differed widely in their diagnosis; yet not one had discovered a latent

Fig. 4.

Fig. 4.—*The intensity of expression due to esophoria.* Note the eyebrows, the wrinkles at the root of the nose, the peculiar, fixity of gaze, and the other evidences of excessive nervous expenditure in maintaining binocular single vision.

refractive error that existed, or had even suggested to me the wearing of glasses.

The use of atropine in my eyes (instilled by myself when in despair and desirous of ascertaining positively which of the three diagnoses was correct) revealed happily to me a refractive error of very high degree that had escaped detection by means of the ophthalmoscope in these three different examinations.

One of these examinations of my eyes was made by an author of a large work upon ophthalmoscopy;

yet even he closed his report by saying "that he could not find anything wrong in my eyes."

Is it to be wondered at, therefore, that I early made a determined fight against the use of the ophthalmoscope for accurate determination of refractive errors. It is a very useful instrument for many purposes; but, so long as the patient has not lost control of his accommodation by the use of a

Fig. 5.

Fig. 5.—*The peculiar blank expression due to "exophoria."* An approach to the so-called "wall-eye." Notice the contrast between this face and that of Fig. 4. Here is a total absence of wrinkles and an apparent lack of concentrated energy in vision.

mydriatic, the ophthalmoscope cannot be relied upon in any hands as an instrument of scientific precision when prescribing glasses.

Moreover, it is as unfortunate as it is true to-day that very careless and imperfect refractive work is constantly done by oculists of international repute.

The probable explanation of this statement, to my mind (and I see daily positive proof of the accuracy of my assertion), lies in the fact that many cases of physical suffering caused by those refractive conditions that rather enhance the acuteness of vision than impair it (especially in youth) are overlooked in the rush of office work and in public institutions because atropine is not generally employed. Again, it is extremely hard to "teach old dogs a new trick," and it is both easy and natural to find excuses for not doing what is theoretically right but of necessity a nuisance to the patient and a time consumer to the oculist.

Yet, on the other hand, sufferers from nervous diseases in consequence of eye-strain (like myself in the past) must continue to suffer until the cause is positively determined and scientifically corrected!

To have only a careless examination; to have a light thrown into the pupil, and to be then told "to run along and stop thinking of eyes" gives no relief to such sufferers.

Fig. 6.

Fig. 6.—*Eyes apparently normal in position, save for a slight tilt of the head*—suggestive of a hyperphoria.

Hasty advice and careless methods have their sad aspects!

Those who consult an oculist of great distinction naturally expect and have a right to expect all the information about their own eyes that the latest and most scientific methods can possibly reveal, and the diagnosis that they receive is generally regarded by the sufferer as final and positive. It is an inexcusable violation of good faith on the part of an oculist, as well as a gross injustice to the sufferer, to omit any step that may throw light on the diagnosis. It is a more serious matter still to such sufferers to be told that they may dismiss from the mind the question of existence of eye-strain as a cause of their symptoms; when the refraction of the eyes has not been determined under atropine, and when the eye-muscles have not been tested by modern instruments of precision.

I hold to-day, as a curiosity, a letter written by an oculist of international repute to the physician who sent a patient to him for examination, in which he states "that the patient has no eye defects and needs only constitutional treatment." Yet this patient who had suffered excruciating pain for many years had a most extreme mal-adjustment of the eye muscles; she had suffered for years from double-vision (at times) and most annoying confusion of letters on a printed page; and she made a complete recovery under my care, after the muscular error was radically corrected.

Such experiences certainly teach some valuable lessons—especially to those who have suffered!

Because a groundless prejudice still exists among some of the older oculists against all attempts to investigate or correct mal-adjustments of eye-muscles; because they refuse to accept conversion to methods which are generally employed to-day in

Fig. 7.

Fig. 7.—*Eyes apparently normal in position and normal head posture.* This patient had, however, marked refractive errors and some latent "esophoria."

spite of the fact that they are not venerable on account of their antiquity; because they may not yet be keenly alive to the deleterious effects of eye-strain upon the general health; these are not justifiable excuses for utter neglect to state their position of non-conversion to their patrons or for failure to investigate thoroughly the cases intrusted to their care with proper instruments and by modern methods. Sufferers (and their medical advisers also) have at least the right to decide whether they wish the eye-muscles tested as well as the refraction of the eyes; have the right to know whether anomalies of adjustment of the eye-muscles have or have not been sought for carefully and intelligently; and are certainly entitled to an opinion from an oculist based upon all the facts and not upon a partial and imperfect set of tests.

The sad aspect to which I have referred is not because a patient has wasted a consultation fee; not because a cursory and imperfect examination has been given in return for that fee; not because any damage has occurred from this unjustifiable negligence; but because an opinion has been given on

Fig. 8.

Fig. 8.—*The intense expression of "hypo-esophoria."* Notice the slight tilt of the head and the fixity of the gaze.

insufficient data; because that opinion is apt to be construed as a final one, on account of the reputation of him who gives the opinion; and because the sufferer (unlike myself in the past) may never again have the chance to learn how his symptoms can be relieved and what was the cause.

If tests for refraction and anomalies of the eye-muscles were not purely mechanical, there might be a wide latitude for differences between oculists regarding the results of a series of such tests. But, fortunately for suffering humanity, modern instruments of precision used to-day by all progressive oculists in making eye-tests are so accurate, that any number of observers who are familiar with their use cannot fail to agree upon the facts disclosed. To detect "latent" or hidden muscular mal-adjustments in the orbit, however, and to decide definitely upon the steps that are to be taken for their correction requires often frequent tests and carefully kept records.

Regarding such obscure eye-problems, I take the liberty of quoting from a recent brochure of mine upon the eye treatment of epilepsy.*

"So it is with many cases of epilepsy, chorea, insanity, and kindred nervous affections. These patients have, as a rule, acquired and constantly practised from birth certain faulty combinations of the various eye muscles in order to enable them to use the eyes together.

"They are often able by the aid of such unnatural combinations to simulate a condition of apparent equilibrium of adjustment of the eyes; although a very serious expenditure of nerve-force may be demanded of them in order to do so. They are naturally unconscious of the eye-strain, because they think everybody does as they do, in order to see. They often have no eye symptoms. They practise these "tricks of adjustment" instinctively, not as an act of volition; and they have generally to be taught, by the aid of prismatic glasses and other recognized steps, to abandon them, and thus to disclose the actual mal-adjustment of their eye muscles which has entailed upon them this long-continued leak of nerve-force and, later on, an abnormal reflex excitability of the nerve centers.

"They are not unlike a tortuous and difficult channel in which the hidden difficulties to surmount do not always disclose themselves upon the surface. They demand and generally repay a careful and scientific scrutiny into the adjustment of the ocular muscles and latent errors in refraction. They require time and great patience on the part of the observer, as well as skill.

"The old and crude methods of testing the eye muscles will have to be totally abandoned at no distant date. A phorometer, a tropometer, some form of clinoscope, square prisms, an assortment of interchangeable prisms and spectacle frames, and various other scientific devices are to-day essential to all accurate work. The separate muscles must be individually tested and their power accurately measured; the arcs of rotation of each eye upward, downward, inward, and outward carefully determined; the presence or absence of any declinations of the vertical and horizontal meridians must be made certain; and the presence or absence of latent muscular anomalies of the orbit must be most carefully investigated by means of prismatic glasses (worn by the patient) before any examination of the eye muscles is to-day complete."

Some time ago a prominent physician called upon me for an examination of his eyes, as a possible factor in a serious physical break-down.

He was astounded, markedly annoyed, and extremely incredulous when I told him that he was on the verge of a double cross-eye; more so when I demonstrated to him that he had unconquerable diplopia when a plain red glass was held over either eye; and he became very much disturbed when a graduated tenotomy upon both interni was suggested as the most satisfactory way of correcting the defect.

To relieve his anxiety and incredulity, I furnished him with two printed blanks; and I then sent him to two other oculists that I knew were familiar with modern methods of testing eyes. I instructed him to say to each of these oculists that I wished the blank that I had given him filled up with great care and accuracy. He returned to my office with each blank filled out, and identically alike with my own. He had then no doubts as to the accuracy of the diagnosis. The results of treatment made the discovery a fortunate one for him.

There is hardly a day in which I do not see in my office some evidence of the utter neglect of marked and important eye factors in varying types of nervous disturbances.

In the case just referred to, the patient had been given by an oculist some weak prisms for near work (incorporated with his reading-glasses). These prisms only corrected about one-tenth of the manifest muscular-error disclosed; and then only for about one-fifth of his hours of daily activity. No prisms had ever been suggested for constant use, to aid his weak muscles; in spite of the fact that the eye-strain was ever present and the patient constantly on the verge of seeing-double (diplopia), even at distant points.

That eye-strain can produce its evil effects upon the physical health long before adult life has been reached is clearly shown to the lay mind, by the large number of children who break down rapidly when sent to school, and who immediately rebound into a better physical condition when study is no longer demanded of them. But intelligent parents do not yet appreciate (as they should) that a large proportion of children who suffer from headaches, car-sickness, weak digestion, St. Vitus' dance, and epilepsy owe their physical ills to some eye-defect.

The time is not far distant when legislative enactment will require in every State and county a thorough test of the eyes of every child before education is begun, as a requirement for admission to the public schools. Even to-day, rough tests of vision are being made upon scholars by teachers themselves in some schools. Letters of warning are to-day forwarded by many teachers to the parents of such pupils as are found to have very imperfect vision, with a request to have complete tests made by some oculist.

No greater punishment can possibly be inflicted upon a child, or a more positive cruelty enforced, than to subject an unwitting sufferer from some severe type of eye-strain to the daily routine of a class-room without the proper glass to relieve that strain. Yet this cruelty is practised to-day unconsciously upon children by thousands of parents and teachers, and the results are recorded in the list of those children who collapse physically sooner or later if their powers of endurance are unequal to the burden they have to bear without aid.

There are certain rough tests of vision that can and should be made by parents or teachers upon every child as soon as it knows its letters, before systematic education is attempted. These tests are as follows:

1. Various forms of test-cards are made to-day and sold by all opticians with letters upon them which are mathematically drawn for normal vision at certain distances.

Such a card should first be purchased. It should be then hung in a good strong light with the child at a distance of twenty feet from the card.

2. The child should then be asked to read each

*_New England Medical Monthly_, November, 1902.

line of the test-card with each eye separately—one eye being covered with a small opaque object (such as a visiting card) held in front of it, while the other eye is being tested.

If either eye fails properly to see the letters on the line of the test-card made to correspond with the distance of the child's eye from the card, that eye is defective. For example, if a child is exactly twenty feet from the test-card, and the right eye alone reads correctly the twenty-foot line, the right eye has normal vision; if the left eye can read correctly only the forty-foot line, the left eye has only $^{20}/_{40}$ of normal vision, or one-half of normal vision. In such a case the two eyes are unlike in focus. This should be investigated by an oculist.

3. It should be impressed strongly upon parents and teachers that normal vision in each eye does not necessarily mean that the eyes are normal. They may be and they may not be.

Some of the most severe types of nervous disturbances occur in children, as well as in adults, from what is known as the hypermetropic eye, or "far-sightedness."

Such eyes may be likened to a half-closed opera-glass. They are more shallow than the normal eye. They have to be artificially focused every moment in order to get normal vision—just as an opera-glass has to be focused by its adjusting wheel. Every second during the busy day such eyes demand unceasing muscular efforts; every second in about sixteen hours of each day unnatural and unnecessary expenditure of nerve-force is going on to focus the eyes; every hour while awake the possessor of such eyes is suffering from this unnatural leakage of nerve-force; and sooner or later (as in my own case) the sum total of this constant leakage is liable to bring about physical and nervous derangement.

It is this type of eye that is not detected, as a rule, by the test-card. This type of eye usually has the "vision of the hawk," because the "focusing muscle" has become, like the arm of the blacksmith, enormous and unnaturally developed by adjusting constantly for the eye deformity.

It is this type of child that too frequently is found on the front bench of the class-room nearest to the blackboard—the place where the eye-strain is greatest, because the adjustment is greater for near points than for distance—while the "near-sighted child" is apt to be seated in the back row of the class-room, viewing the blackboard through a fog, as it were, because no muscular effort can help his special eye-deformity.

4. When parents find the vision of either eye in their children to be more acute than normal, there is ground to suspect that the "hypermetropic" or "far-sighted" eye exists, and it is wise to have that point settled positively by an oculist.

For example, if either eye alone, or both eyes together, enables a child or adult when placed twenty feet from a test-card to read the ten-foot line with accuracy and ease, the vision is then $^{20}/_{10}$, or double the normal power. This is as unnatural as is the example previously, quoted in which an eye had only $^{20}/_{40}$ vision, or one-half the normal power. Both probably point toward some congenital eye deformity.

5. To test the eye-muscles requires more apparatus and knowledge of optics than to test the visual acuteness of the eyes. It is therefore needless to enter here into a field too complicated for the layman or general practitioner in medicine.

There are, however, two rough tests that a parent or teacher may employ as a step toward determining whether the eye muscles are capable of controlling binocular single vision at all points. I refer to the "red-glass test" and the "exclusion test." To use these, a candle flame is commonly employed as a test object; placed at a distance of twenty feet from the eyes.

The Red-glass Test.—Hold a piece of plain red glass over one eye. Instruct the child to look at a candle flame with both eyes open. Ascertain whether the child sees one white candle flame or two candle flames (one red and one white). Now instruct the child to turn the head slowly toward the right and the left, while looking at the candle flame with the red glass still held over one eye. Ascertain while doing so if the child sees a double image at any point.

If the *child sees a double image* (diplopia) at any time or at any point during these tests, there is a decided tendency to crossed-eye, which should be investigated by modern methods and instruments (preferably before education is attempted).

The Exclusion Test.—This is a very simple and valuable means, in some instances, of discovering if the two eyes are working together properly.

Many children and adults have such extreme mal-adjustment of the eye muscles that only one eye is frequently used at a time—instead of both eyes together, as Nature has intended. They may not exhibit to a casual or untrained observer the characteristic deformity of a typical crossed-eye; but, at times, a cast is apt to appear in either eye, and the sufferer may be unable to look steadily with both eyes at any near point without extreme effort. How often do we hear the remark made that because some person "does not look you straight in the face, when talking to you, it is not safe to trust him"! Yet the true explanation of this unfortunate habit may be that the person suspected suffers from the very defect that is now being discussed here; and which makes it impossible to look steadily for any length of time without shifting the eyes to obtain rest. It is a very common habit for an extremely far-sighted person to avoid looking steadily into the eyes of a companion during a conversation—and the same may be said of those who suffer from extreme mal-adjustment of the eye-muscles, for which they have to make unnatural adjustments.

The "exclusion test" may be employed by the parent or teacher upon anyone suspected of difficulties in adjustment of the two eyes. It is made as follows:

Place the child twenty feet from the test object (preferably a candle flame), and instruct the child to gaze fixedly at it with both eyes, while a visiting card or some opaque object is held in front of one eye so as to shield the candle flame from view. Observe behind the shield if any deflection or trembling of the covered eye appears. If so, it indicates a weak or mal-adjusted eye-muscle.

Now shift the card (or shield employed) rapidly to cover the field of vision of the opposed eye. Note carefully if the eye moves (inward, outward, upward, or downward) when it is suddenly uncovered. The "jump" observed on shifting the shield is due to an effort on the part of Nature to regain a lost visual impression of the test-object. Repeated shifting of the shield from one eye to the other will show if both eyes jump or only one; also in what direction each eye moves when shielded and when uncovered.

A jump inward (at the moment the card is shifted) indicates that the eye when covered tends to diverge from its fellow (*exophoria*), and when uncovered has to be moved inward to get a visual image; a jump outward indicates a marked tendency toward convergence (*esophoria*); a jump in the vertical direction points strongly toward a marked difference in level between the eyes (*hyperphoria*), provided that

the two eyes jump in opposite directions. If both eyes jump upward or downward when uncovered, the two eyes may tend to assume too high a plane or too low a plane in the orbit (*anaphoria* or *kataphoria*). These terms are explained in a subsequent table.

Normally balanced eyes should show no tendency to move when the shield is shifted from one to the other.

It is not uncommon to see some eyes deviate behind a shield from one-quarter to one-half an inch from the position which each should maintain normally, and make a corresponding jump in the opposite direction when the shield is shifted. In many instances, the "exclusion-test" becomes a most valuable aid in solving complicated eye-problems—such as are frequently encountered in connection with epilepsy, insanity, chorea, etc.

In my work entitled "Eye-Strain in Health and Disease."* I devote one entire chapter to the various tests employed to determine and measure anomalies of adjustment of the eye-muscles and errors of refraction. I would refer my readers to this work for more complete information on these tests, and the modern instruments employed for that purpose. Many pictorial illustrations are employed by me in that work to aid the general practitioner in this field of diagnosis.

Finally, I deem it wise to call professional attention here, as I have repeatedly done in the past, to the diagnostic importance of certain facial expressions and peculiar attitudes in children and adults that tell of visual perplexities. These are oftentimes of great scientific interest and value.

There is no field of surgery that is to-day complicated with greater difficulties, and in which greater precautions against mistakes have to be taken, than in scientific attempts at the solution and correction of extreme cases of "cross-eye."

The time has fortunately passed when all that sufficed for a cross-eyed child or adult was to completely sever the muscles that appear to be holding the eye in a wrong position. Such crude work frequently accomplishes nothing; again, it is too often followed by a horrible over-correction; and, in quite a large proportion of cases, it caused the patient to suffer later from the results of a severe type of eye-strain which never existed before the operative bungling.

I lately saw, with horror, a conjunctival wound of at least one-half inch in length first made by an eminent surgeon on a cross-eyed patient; then all the delicate connective-tissue attachments were "loosened up" without regard to what these delicate fibers were designed by Nature to do; and finally the so-called "tight-tendon" was completely severed after being pulled out by means of a hook far beyond the limits of the gaping wound. The result was an awful deformity; far worse than the original one, and (what is worse) almost impossible to correct after such a wholesale dissection. Criticism is unnecessary. The surgeon, apparently, knew nothing of the results of modern research in the field of mal-adjustment of the eye-muscles or the scientific correction of such conditions.

The following table will explain to the general practitioner in medicine the meaning of certain terms that are used in connection with anomalies of refraction of the eyes and mal-adjustments of the eye-muscles:

Terms related to the focus of the eye (*refractive terms*):

HYPERMETROPIA (*far-sightedness*). A *shallow eye* (from the front to the back), causing an imperfect focus of objects.

MYOPIA (*near-sightedness*). An *elongated eye* (from the front to the back), causing an imperfect focus of objects.

ASTIGMATISM. An *irregularly-curved cornea* or *lens*, causing distortion of images on retina.

EMMETROPIA. A *perfectly constructed eye.*

Terms related to the muscles which move the eyes (*muscular terms*):

ESOPHORIA. A tendency of one or both eyes to deviate toward the nose.

ESOTROPIA. An actual turning of one or both eyes toward the nose (*convergent squint*).

EXOPHORIA. A tendency of one or both eyes to deviate toward the temple.

EXOTROPIA. An actual turning of one or both eyes outward (*divergent squint* or "wall-eye").

HYPERPHORIA. A tendency of one eye to rise above the level of its fellow.

HYPERTROPIA. An actual turning of one eye above its fellow (*vertical squint*).

ANAPHORIA. A tendency of *both eyes* to assume too high a plane.

KATAPHORIA. A tendency of *both eyes* to assume too low a plane.

HETEROPHORIA. Abnormal adjustment of the eye-muscles.

ORTHOPHORIA. Normal adjustment of the eye-muscles.

ADDUCTION. The power of the internal muscles of the eyeballs. *It varies in health between 25° and 60°.*

ABDUCTION. The power of the external muscles of the eyeballs. *It should be 8° in health.*

SURSUMDUCTION. The power of the vertical muscles of the eyeballs. *The right and left should be alike.*

Various forms of glasses employed by oculists:

SPHERICAL. Ground upon a *convex or concave sphere.* Used to correct hypermetropia and myopia.

CYLINDRICAL. Ground upon a *convex or concave cylinder.* Used to correct astigmatism.

PRISMATIC. *Two plane surfaces of glass meeting at an angle.* The thick side is termed the base of the prism. Used to relieve mechanically errors of adjustment of the eye-muscles.

Diagnostic Attitudes of the Head and Peculiar Facial Expressions Caused by Mal-adjustments of the Eye-Muscles.—For many years, in connection with my office work, I either took or had taken cabinet-size photographs of all of my cases that had extreme eye-defects. I was extremely particular to have these pictures taken with the patient facing the camera; and I was equally careful to allow of no retouching of the negative.

My object in taking these photographs was a double one. In the first place, these pictures gave me incontrovertible proof of the accuracy of my statements during a period when the results of modern work upon mal-adjusted eye-muscles were more frequently sneered at than accepted by medical men.

In the second place, a series of such pictorial records of each important case taken at intervals during treatment were most interesting to me and to others who were willing to study them.

It was therefore vital that each series of such photographs of the same patient should be taken in as nearly the same position and size as possible—in order to contrast them with each other, and to observe changes in the expression and pose of the head.

During that very interesting period when the antagonism of almost all of the leading oculists and neurologists to this new line of investigation and treatment of headaches, neuralgias, epilepsy, insanity, chorea, and other severe types of nervous diseases, was very active, I frequently exhibit such a series of photographs of the cases reported by me before medical societies. I was therefore compelled to omit any retouching of negatives, because it might tend to change the facial expressions, and thus bring into the fight a claim on the part of the enemy of manufactured evidence in support of my views and assertions.

The changes in facial expression that followed a readjustment of eye-muscles were shown to a most

* F. A. Davis & Co., Philadelphia.

startling degree in some of these photographs. With the gradual improvement in nervous tone on the part of the patient came, in some instances, a typical shortening of the face, an obliteration of certain abnormal lines and wrinkles, a brighter expression to the eyes, and a decided modification in the pose of the head. So marked were these changes in some patients that it seemed hard to realize that the first of the series of photographs when contrasted with the last of the series were those of the same individual.

To anyone interested in the investigation and correction of mal-adjustments of the eye-muscles, I would suggest the use of photography as a most valuable aid in studying certain diagnostic attitudes of the head and peculiar facial expressions created by congenital defects of the eye-muscles. Furthermore, such pictorial records of cases constitute a most valuable addition to the ordinary pen-records usually kept by medical men. The photographs reproduced in this article illustrate their diagnostic value. The few hints that I give here may, I trust, aid the reader.

1. *Peculiar and persistent attitudes of the head* often materially assist an expert in making a diagnosis of some abnormal condition of the eye-muscles that may at first appear obscure.

(*a*) A *persistent tilt of the head to one side* usually justifies a suspicion that one eye tends to rise higher than its fellow—the condition known as "hyperphoria."

Strange as it may seem at first to the reader, the tilting of the head is toward the side that corresponds to the lower eye. This is because the low eye tends to see an image higher than it should be, and the high eye tends to see an image lower than it should be. By tilting the head toward the side corresponding to the low eye, sufferers from hyperphoria or hypertropia are enabled to bring the visual images of both eyes more nearly on the same plane, and to fuse them with les ffort.

This peculiar attirude of thc head is shown in some of the photographic reproductions given here (Figs. 1 and 2).

(*b*) The *forehead may be persistently thrown forward and the chin drawn in closely to the chest*, in consequence of eye-defect.

This peculiar attitude gives to the sufferer from "anaphoria" (see table of terms) the appearance of looking out from underneath the eyebrows.

The necessity of pulling eyes down constantly to the normal position (when both eyes tend to rise too high in the orbits) is greatly relieved by this peculiar attitude—which has great clinical significance.

The compression of the larynx and trachea that follows the persistent pulling the chin toward the chest and throwing the head and shoulders forward has been quite extensively discussed as an important predisposing factor to throat affections and lung diseases.

(*c*) The *chin may be persistently protruded*, whenever the eyes tend to assume too low a plane in the orbits.

The condition termed "kataphoria" (see table of terms) is often accompanied by this peculiar attitude of the head. It allows the eyes to look at objects from a lower plane in the orbit than the normal one, and this relieves the superior recti muscles.

2. *Diagnostic facial expressions associated with eye-strain* often tell their own story, as well as unnatural attitudes of the head.

I know of nothing in medicine that has greater attraction than the study of physiognomy from the eye-standpoint. My own leisure moments are frequently employed, while in public conveyances or at social entertainments, in detecting those whose eyes (either constantly or at momentary intervals) tend to assume positions in one or both orbits that are incompatible with binocular single vision.

Certain facial expressions are peculiarly diagnostic, moreover, of eye-strain—in spite of the fact that no abnormal attitudes of one or both eyes can be detected.

A few selected photographs reproduced throughout this article will illustrate some of these expressions better than words:

(*a*) When the eyes tend to deviate toward the nose (esophoria) to a degree that makes binocular single vision extremely difficult, there is usually a peculiar intense expression of the face.

This is extremely difficult to describe. The open, frank expression of the normal eye seems to be absent; and in its place comes an expression that tends to create rather a feeling of distrust. (See Figs. 4, 5, and 9.) To such sufferers whenever the esophoria is so extreme as to make them liable, a slight cast in either eye or to momentary attacks of confusion in maintaining binocular single vision, it often becomes extremely difficult to look steadily in the eyes of any one conversing with them without looking off or dropping the eyes. It is because of this peculiar physical disability that the character of these persons is often misconstrued.

The hard and disagreeable expression that often accompanies extreme "esophoria" is frequently entirely dissipated by its radical correction.

The tendency of the eyes to deviate toward the nose (esophoria) is unquestionably one of the most common and too often a totally neglected factor in causing extreme headaches, neuralgias, digestive ills, chorea, epilepsy, and nervous prostration. I have seen many house-confined invalids restored, as if by magic, to perfect health after relief from esophoria—hence its presence cannot be recognized too early in life, or its relief ignored with safety to the sufferer.

(*b*) When the eyes tend to deviate from the nose (*exophoria*) the face has a peculiarly blank expression. Whenever such a sufferer is not looking very intently, one eye may often be observed to wander off toward the outer part of the orbit, only to return again to its normal position, when the gaze becomes more intent upon any object.

The typical "wall-eyed" expression is only observed in extreme cases of divergent cross-eye.

Genuine "exophoria" is far less frequent than either "esophoria" or "hyperphoria"; yet, in my experience, I meet more frequently in my office patients who are wearing prismatic glasses (prescribed by oculists) for this supposed defect than for any other mal-adjustment of eye-muscles. The antiquated method of testing the eye-muscles at the reading point (instead of at the distant point) probably accounts for these frequent errors, both in diagnosis and treatment.

General Summary and Conclusions.

1. Eye-strain cannot be recognized too early in youth.

2. Its scientific investigation by modern methods and its radical correction may favorably modify both physical and mental development.

3. The neglect of an existing eye-strain may in time allow it to exhaust the reserve nerve capital of the sufferer and produce untold ills both of body and mind.

4. No child should ever be allowed to begin education until it is known that its eyes are properly fitted for the work.

5. Legislative enactment should, and surely will

in time, compel an eye examination of every child before it enters the public schools.

6. Teachers should also be instructed in the rudimentary steps of vision testing.

7. Tests for mal-adjustment of eye-muscles should be made upon every child as thoroughly and intelligently as tests for errors of refraction are made prior to its education.

8. A knowledge of the possible effects of eye-strain upon mental and physical development cannot be too widely disseminated among parents and teachers.

9. The direct causal relationship between "eye-strain" and nervous diseases is too well established to-day to require further proof, or even to justify further discussion.

10. The modern methods of testing for anomalies of adjustment of eye-muscles are the only ones that can furnish us with scientific and accurate information.

The time has happily passed when any oculist can instruct a patient to simply follow some object held before the eyes with the eyes; and then on that test alone give a final decision as to whether mal-adjustment of the eye-muscles exists or does not exist. Two decades ago this was about all that anybody knew about eye-muscles. To-day, the mere tyro would not dare commit himself on such tests.

11. The cure of disease to-day is intelligently based on *the search for its cause* rather than on an indiscriminate use of drugs; and the prevention of diseases is rapidly becoming more important to the medical mind, and also to the laity, than its cure.

12. The detection of "eye-strain" in youth is an important step in preventive medicine, and the arrest of a nervous leak may save many a child from a permanent break-down when an adult.

13. The study of facial expression and head posture is destined to become an important aid in diagnosis.

14. The governing boards of institutions for the feeble-minded, the epileptic, and the insane will sooner or later be compelled to investigate more carefully and earnestly than in the past the eye conditions of their inmates.

345 Madison Avenue.

TUBERCULOUS (BASILAR) CEREBROSPINAL MENINGITIS AND DELUSIONAL INSANITY COMPLICATING PULMONARY AND LARYNGEAL TUBERCULOSIS.*

By HENRY LEVIEN, M.D.,
LIBERTY, N. Y.

My reason for reporting these two cases to the medical profession is, firstly, because tuberculous meningitis in adults is rather uncommon. Out of 178 cases under my care in the sanitarium since May 1, 1900, and sixty-five cases in my outside practice, only two presented themselves, which would make three-quarters of 1 per cent. Secondly, this report will corroborate the accepted opinion that this disease afflicts men more often than women, and that it occurs between the ages of twenty and thirty-five years.

Case I.—Mr. T. F. C., kindly referred to my care by Dr. H. of New York. The patientetne red sanitarium March 10, 1902. He is twenty-six years old, married five years, has three children, all well. Born U. S. A. Clerk by occupation.

Family History: One brother died of "scrofulosis" —other brothers and sisters, as well as his parents, are well. Felt healthy till last October, when he had an attack of pneumonia on the left side. Was in bed nine weeks, due to a relapse. He was in the mountains a year ago, because he was run down. Since convalescence was not able to do much work, felt weak, was coughing, had night sweats, lost about twenty pounds in weight, coughs considerably now, with little expectoration. Appetite variable, bowels regular; is very hoarse.

Inspection: He is undersized, his height five feet one inch, chest measurement thirty inches. He is very anæmic and nervous. Has slight tremor in his wrists, and on walking exhibits an ataxic gate, dragging the left foot. Complains of severe headaches. There is the typical sparkle in his eyes, and the fingers are slightly clubbed.

Physical Examination: Temperature 100°, pulse 90 beats per minute and of jerking character, arteries slightly sclerotic. Weight, 86.75 pounds.

Chest examination: Consolidation of the right lung anteriorly from apex down to third rib. Many moist sibilant râles, posteriorly; suppressed respiratory murmur. Left lung normal. Disturbed cardiac action, though no murmur detected. Ulceration of the larynx and tumefaction of the vocal cords. Urine examination is negative. Is very emaciated and very nervous. He was put at once under hydropathic treatment, which seemed to benefit him remarkably. He felt stronger, his appetite improved. Medicinally, he took hypophosphates and malt, and had local applications to his ulcerated larynx of lactic acid in 25-per-cent. solution.

March 16.—During the week past he felt pretty good. Was able to take nearly full meals, swallowing with very little pain. But he was always sleepy and complaining of headaches. His temperature was 99°, pulse 82, weight 86.

March 18.—Would not come down to breakfast, saying that he did not sleep during the night, and remained in bed till noon. Laryngeal pain increased and could partake only of liquid food. Spent the whole day in the open air, but his somnolent condition increased and tremor was more marked. Appetite poor. Bowels sluggish. Temperature 100°, pulse good.

March 19.—Would not leave his bed, complaining of severe occipital headaches; anorexia was complete. He had to be urged to take some nourishment. We have just learned the fact, which was later corroborated by his wife, that he was addicted to alcohol. Not being allowed to indulge in any liquors, because of his nervous condition, he would ask of his fellow patients who were directed to use some stimulants. When at home he used to drink wines, which he exchanged later on for whiskey.

March 20.—Hardly coughs at all, unable to get out of bed, rests on his back, head buried in the pillows. Opisthotonus taking place. When not asleep stares at vacancy. Hardly able to talk above a whisper. Respiration shallow, but no dyspnœa. Pulse normal, temperature 100°. Toward evening became restless. Was tossing around in bed and muttering incoherently. He did not move his bowels for thirty-six hours. Refuses food. At 10 P.M. he became violent, jumped out of bed, and when responding to the nurse's call for assistance I found her struggling with him trying to put him back to bed. A remarkable superhuman strength was exhibited by this small frail body. It took the combined efforts of the two of us to replace him in bed, and then considerable strength was required to keep him quiet, when in bed already. Bromides, in quite large doses, had not the desired effect, and resort ought to be had to the hypodromic use of

*Read before the meeting of the Eastern Medical Society of New York City, February 13, 1903.

morphine, which gave him the much-needed rest for the whole night. The nervous explosion once started did not cease. The next day, March 21, the nervousness continued. He would toss around, pick the bed-clothes, manipulate the genitals, bringing on priapism. The looks were wild, had his mouth open, yet he seemed to be conscious of what was going on around him. He would lock his jaws when offered food, yet when asked if he would take some port wine (his favorite drink) he would nod assent, and when given would drink eagerly, apparently without pain on swallowing. An enema was administered, which relieved his bowels, and he passed a large quantity of urine. After that he lost control of both sphincters, and seemed not to notice what he was doing. He had during the day three violent attacks, trying to jump out of bed. Was tossing around, gesticulating. Pupils dilated. Temperature 101°, pulse commenced to weaken. We administered concentrated food with his port. At 10 P.M. his wife arrived. He did not know her. Had a fourth violent attack, and again morphine was resorted to, and he slept quietly during the night, and the ice-bag was retained on his head. Next morning, March 22, he seemed to feel much better. His look was more normal, and though he did not recognize his wife, yet he seemed to appreciate her presence, as he would take nourishment from her hands quite readily. About 10 A.M., as if awakened from a deep slumber, he sat up in bed, spasmodically embraced and kissed his wife, his face radiating with gladness; after a few minutes he fell back exhausted, but would not let her hands go. Her nearness had a soothing effect upon his disturbed nervous system; he would take his nourishment readily, his pulse improved and was resting quietly, but his bowels moved involuntarily, he could not control the vesical sphincter. At times he would close his eyes and twitch the muscles of his face as if in pain.

March 23.—Improvement continues. He could be induced to urinate in a bed-pan, would take his nourishment regularly, would answer questions rationally, though not above a whisper. Hope of full recovery was gleaming in the poor wife's mind. His temperature was 100, pulse 90 and strong. Yet opisthotonus continued and so did the semi-consciousness or the comatose condition. Pupillary reflex gone. He would look, but did not see. He has never yet spoken a word to anybody, nor made any voluntary motion. Mrs. C. and his brother, who arrived by this time, were determined, at all hazards, to take him home as soon as he becomes a little stronger.

March 24.—Same condition, with slight improvement as regards his restlessness, which was rather controlled at the start by his wife's caresses and soothing words.

March 25.—Hardly any change noticeable in his condition. Semi-conscious. Rolls his eyes constantly, picks his lips and tongue, but when asked whether he would like to go home he smiled assent. In compliance with his wife's urgent solicitation, I consented to escort the patient to New York. He stood the carriage drive from the sanitarium to the railroad station, a distance of nearly two miles, pretty well, but when at the station his brother wished to take him down to the cars, he showed fight, just as if he did not care to leave the carriage. It was again a hard struggle between a powerfully-built man and this little exhausted trace of humanity. Nothing untoward happened during the journey, which continued more than four hours. Having been made comfortable on a lounge, he laid quietly, took his nourishment and stimulants without contradiction, but did not sleep. He seemed to appreciate my presence near him. He would take some medicine from me as if obeying my orders. We safely arrived at Weehawken, when he was rolled in a chair into the waiting-room for rest. He looked up straight into my face, as if to express his gratefulness for his safe landing. For the first time he took the glass of wine I offered to him with his own shaking hand and drank from it. Not deeming my presence necessary for the night, and instructing them to call in the morning their family phyician, I bent down to my patient to bid him good night, when, unexpectedly, he stretched out his arm, and grasping my hand. shook it spasmodically and in a friendly way. He died the next morning.

My diagnosis in this case would be cerebrospinal meningitis, induced by toxins of tubercle bacilli, which infested the pulmonary and laryngeal tissues and traveled upward and downward, carrying destruction through the channels of the lymphatic system. The invasion of the bacilli or their toxins into the cerebrum, causing exudation into the ventricles, inaugurated the cerebral coma by pressure upon the cerebral substance. Knowing well the accepted theories that spinal meningitis is mostly epidemic, yet I venture to entertain the opinion that in this case the spinal meninges were involved, as well as the roots of the nervous trunks issuing therefrom, as evidenced by paralysis of the vesical and anal sphincters, by the priapism which is caused partly by the involvement of the sympathetic nervous system and partly by the spinal nerves (genitocrural) and sacral plexus. I am aware of the opinion that sexual function and desire depends upon a center located somewhere in the brain proper, some think it is the cerebrum, an opinion denied by others, and by some in the spinal cord between the second and third lumbar vertebræ, but in our case in whom volition was deadened, and there could not be any instinctive, even sexual desire, the priapism was the result of the irritation of the spinal meninges, the nerves, and terminal filaments in their intercommunication. The direct cause of death in this case would be exhaustion of nerve force supplying the heart muscle, and consequent paralysis of same.

Delusional and Maniacal Insanity.—CASE II.—Mr. A. B., thirty-one years old, Russian, sweatshop tailor by trade; married four years, has one child. Wife and child well. Father died twenty-four years ago, cause unknown; mother, one brother and four sisters alive and well. He was kindly referred by Dr. J. I. B. and admitted to sanitarium March 4, 1902.

Personal History. Was well till one year ago, when an abscess near the anus appeared, for which he was operated upon and was sick seven months. He recovered and returned to work. Five weeks ago he commenced to cough; had "caught a cold" in the shop. On the third night he had a severe pulmonary hemorrhage, which did not subside for a week Night sweats set in, also frequent irregular chills. Had diarrhœa for the last week. Vomits after eating meat. Appetite poor.

Inspection: Body fairly nourished, slight recession under right clavicle; on walking he drags his left foot rather than walks on it. His look is apathetic. Patellar reflex exaggerated. Considerable dyspnœa. Very anæmic.

Physical Examination: Temperature 101.2, pulse 90 and thready; weight 133.5 pounds. His weight in health 148 pounds. Chest examination shows on percussion, considerable dulness on right side anteriorly and posteriorly from apex down to liver. On auscultation, many moist bubbling râles all over

right chest, obscuring the vesicular murmur entirely; in a few disseminated spots, near to clavicle bronchial breathing with prolonged expiratory sound was discernible. Slight pleuritic friction sounds in the right axillary region. Left lung also in a catarrhal condition.

Diagnosis: Tuberculous broncho pneumonia with pleurisy right side, anteriorly and posteriorly; apex catarrh left side.

Treatment: Put to bed in a large room with both windows wide open day and night. Frequent sponging with friction. Medicinally, small doses of digitalis strychnine and quinine as antipyretic. Fluid diet, milk and broths.

March 10.—Temperature 102, pulse 80. Not so many râles anteriorly, feels stronger. Able to spend twelve hours during the day on the upper veranda. Is given solid food, as his bowels became regular and appetite improved. But while feeling stronger, yet he would hardly talk to anybody, always keeping to himself. A few days later was able to come down to general dining room, eat a hearty meal, but had attacks of high fever. Had also chills.

March 16.—Temperature 101.5, pulse 78, weight 129.5 pounds. Right lung, clearing up of the moist râles, but there were numerous friction râles in the axillary region extending toward the sternum. There having been occasional chills, and with those râles and rather flatness on percussion, I suspected empyema and performed paracnetesis, but the syringe did not bring up any pus, but a few drops of serum were withdrawn. His nervous state attracted our attention by this time. Though taking his meals regularly, yet when sitting outside he would have his eyes half open and muttering to himself. He seemed delirious. He hardly spoke to anybody, though when addressed would answer rationally. His wrist tremor continues, though his feet ceased trembling and seemed stronger. His loss in weight I attributed to high fever, temperature would run up sometimes as high as 104.5°; continues his rest cure and says that he feels well.

March 18.—Confiding to nurse that he received letters from his friends (which he never did) from New York that his wife was very unfaithful to him. He knew it long ago. He doubted whether the child born to him was his. He never ceased talking about it. This delusion seemed to torture him considerably. His appetite became poor and would sleep but little, otherwise he was rational. Believing that the presence of his wife would dispel his morbid thoughts, I ordered his wife to come.

March 22.—He was glad to see his wife, his suspicions were gone. She thought first of staying a few days with him, but her refusal to enter into intimate relations with him caused quarrels between them and excited him greatly, and we deemed best to cut her visit short. After she was gone another illusion entrapped him. This time in his business line. He assured everybody around that his partners (which he never had) are robbing him right and left, that he is going to remain a poor man. And when not speaking on this only subject he would sit and talk to himself or dose with eyes half open. Yet he would mind the bells calling for meals and partake of everything put before him. On the morning of the 23d, about 2 A.M., the night nurse met him in the main hall, fully dressed. To her query where he was going he replied in plain words that he was going to fetch a car and run up to his shop. Without much resistance he was made to return to his room and go to bed. Special guard was put on him since.

March 24.—He was up and about Went down to his meals, but walked with difficulty. This nervous explosion or somnambulistic attack seemed to be the evil herald of his nervous break down. He was not the same man since that night walk He would talk to nobody. His lower extremities commenced to become œdematous, and he would walk up a small flight of stairs with great difficulty. Yet he would not stay in bed, nor would he accept extra services from the nurse. He would rather apply to other patients to assist him to the toilet room. It was noticed toward evening that he is losing control of both anal and vesical sphincters, though his mind, except for his special hallucination, seemed yet rational.

March 24.—Was kept in bed with ice to his head. Temperature 104, pulse 90. He hardly coughed at all, no dyspnœa, breathing shallow. He would take his meals with avidity and then fall into semi-consciousness. He did not sleep, but would stare at vacancy. It was not coma, but a nervous exhaustion. Toward evening his bowels moved involuntarily. He was unable to move. Complains of headache. Slept a few hours during the night.

March 26.—Temperature 103, pulse 100; semi-comatous. Takes his nourishment without relish, lower extremities very œdematous, pupils dilated. Doesn't complain of anything, does not toss around, drinks a good deal of water.

March 27.—Coma deepens; pulse 110, temperature 102. Bowels moved again involuntarily. Took his broth for dinner, drank down a cup of milk, and rested quietly. At 4 P.M. Cheyne-Stokes' respiration set in. Pulse small and 120 per minute. At 5 P.M. he was dying, yet looking up to me as if begging for assistance; at 6 expired. Respiration ceased first, heart last.

The salient points in this case we would consider: (*a*) the two kinds of illusions following one another; (*b*) the attack, or probably attacks (few escaped notice, maybe) of somnambulism, which were the starting points of his nervous exhaustion; (*c*) the swelling of his lower extremities not due to any palpable lesion in the heart nor in the kidneys. Certainly due to obstructed venous return in the lungs, yet there was not any appreciable dyspnœa. (*d*) Direct cause of death would point to paralysis of the respiratory center rather than to the inhibitory nerves of the cardiac mechanism.

There being no necropsy, our reasoning in reference to the two cases cited must necessarily rest upon theoretical grounds; therefore, in contrasting them I venture to state that though there is some similarity between them, inasmuch as both of them exhibited abnormal mental phenomena, yet the first case I would delegate to the category of meningitis with positive organic lesions in the brain substance: softening of the brain, exudation into the ventricles with involvement also of the spinal meninges and nerves issuing therefrom, hence my diagnosis tuberculous cerebrospinal (basilar) meningitis—the second case belongs, in my opinion, to the functional disorders of the brain without any special lesion in the cerebrospinal system. It was certainly insanity of the delusional variety.

The Imperial Health Board of Berlin has issued the following statistics regarding the mortality from phthisis in Europe: Russia has more than 4,000 deaths per 1,000,000; Austria-Hungary and France more than 3,000 per 1,000,000; Sweden, Germany, Switzerland, and Ireland more than 2,000 per 1,000,000; Netherlands, Italy, Belgium, Norway, Scotland, and England more than 1,000 deaths per 1,000,000.

RESECTION OF INTESTINE, WITH REPORT OF THREE INTERESTING CASES.*

By A. E. ISAACS, M.D.,
NEW YORK.
SURGEON TO THE BETH ISRAEL HOSPITAL.

The cases presented herewith are not unusual from a general point of view, but each presents some features worthy of note and comment. The three are consecutive cases of intestinal resection for different conditions, done within a short time, and ending in recovery. The first two serve to demonstrate how uncertain the diagnosis of acute appendicitis may be even when the symptoms are apparently clear, and what unusual conditions may be found when least expected. Besides the diagnosis, another point of interest in the first case is the length of gangrenous gut included in the intestinal strangulation, twenty-three inches.

The second case presents two points worthy of note. One is that the usual ligation and amputation of the appendix may be ineffectual in closing the appendical orifice, and may result in fecal fistula, as it did in this case, in which circumstances were favorable to this outcome. Mere ligation of the appendix only brings its mucous surface together and union is hardly to be expected except if the mucous layer be destroyed by disease. What really closes the orifice in this method, is the union of the raw edge of the stump where amputated, or where ligated, if the ligature be tight enough to strangulate the distal portion, with the serous covering of the adjacent viscera. In this case there were no adjacent viscera to become adherent to the stump as arising from its unusual position in front of the cæcum, it presented in the open wound.

The second point of interest in the case is the demonstration of the amount of operative interference tolerated by some persons. The patient was a boy only eight years old, and he successfully withstood five severe laparotomies within a period of five months, coming out apparently none the worse for his experience except for the presence of scars and the possibility of future hernia.

The third case was a strangulated femoral hernia so far advanced that sloughing of the constricted gut with suppuration in the sac had already taken place. In spite of the lowered vitality due to the condition, in a woman normally of poor physique, and in spite of the necessarily septic field to work in, she made a very prompt and good recovery.

Case I.—Frank S., age fifty-two, pedler, admitted to the Beth Israel Hospital, July 18, 1902. Has had right inguinal hernia for the past twelve years, that never caused him any trouble. Two days before admission, he was taken suddenly with general abdominal colic, persistent vomiting and constipation. After six or eight hours the pain became localized to the right iliac region. Character of vomitus became changed to brown, ill-smelling fluid, and constipation complete. Also retention of urine. Was sent to the hospital with diagnosis of appendicitis. Examination then showed right inguinal ring patulous, hernia reduced. Distension of abdomen, extreme tenderness in right iliac region. Lying with right thigh flexed, and abdominal rigidity so great as to make it impossible to find whether a tumor was present or not. Pulse 90, temperature 102.6°.

Vomiting continually. Enemas brought on no movement of the bowels nor flatus. Diagnosis of acute appendicitis made, but patient refused operation and would not submit till the next day. Under ether anæsthesia, the usual right-sided incision was made. Adhesions were found between the cæcum and small intestine. Separating these a gangrenous coil of intestine was encountered deep in the cavity, showing that the appendix was not the cause of the trouble, but that it was an intestinal strangulation. The incision was considerably enlarged to be able to deal with the condition, and the gangrenous gut was separated and drawn out little by little till there was nearly two feet of it. It was found to have gotten under and become strangulated by a small band that seemed to be connected with the bladder. This band divided, relieved the constriction, but the gut was hopelessly gangrenous and had to be removed.

What this constricting band was would have been very interesting to have ascertained, but the patient's condition and the severity and length of the operation as it was, would not allow of taking the additional time necessary for the purpose, especially when there would be plenty of opportunity at an expected post-mortem which, fortunately, did not come. The tedious work of separating such a length of gut from its mesentery took considerable time. End-to-end anastomosis was made with a Murphy button. The redundant mesentery was folded on itself and held so with stitches. Appendix was not encountered during manipulation, nor for want of time was it looked for. Incision closed by layers, leaving small opening for drainage. Anæsthesia lasted two and three-quarter hours. First movement of bowels twenty-six hours after operation. Button passed July 28, nine days after operation. Discharged cured in four weeks.

Case II.—This little boy, Max Gold, age now eight years, was seen by me at his home on April 10, 1902, through the courtesy of Dr. Lowenkopf. He had then been complaining of abdominal pains for some days, which at first were general and mild, but gradually became more intense and limited to the right lower quadrant. He had fever and constipation. There was quite a distinct tumor very painful to the touch between the umbilicus and right anterior superior iliac spine.

All the symptoms were those of an acute attack of appendicitis with local suppuration, and I sent him to the Beth Israel Hospital for operation. The hospital records show that on admission his temperature was 101.8°, pulse 84. He was prepared for operation for the next day, April 11. Before operation his temperature had dropped to 100.80, but the pulse had gone up to 120. Under chloroform anæsthesia, an incision was made over the tumor, and in opening the peritoneum, to our surprise, there was the whole appendix, as healthy-looking as any appendix could ever be expected to be, lying freely almost in front of the cæcum, a very unusual position, and a position that had a bearing on the future course of the case, which I shall refer to later. Just above the appendix was the tumor which consisted of omentum and cæcum inflamed, adherent, and matted together with the parietal peritoneum. The temptation to excise the appendix was too great to be overcome, and it was ligated with catgut and removed. After the usual protection of the peritoneal cavity with gauze packing the adhesions of the tumor were separated till a large abscess was found posterior to the cæcum or ascending colon. Exploring the abscess, it was found to come from the spine. A lumbar abscess that, in place of working its way down along the psoas muscle to the groin, forming the common psoas abscess, or pointing through the lumbar fascia, forming the ordinary lumbar abscess, took the very unusual course of working its way forward

*Cases presented at a meeting of the Eastern Medical Society, November 14, 1902.

through the abdominal cavity, and pointing toward the site of the usual appendicitis abscess.

The wound was partially closed, allowing sufficient opening for drainage, and treated in the usual way. Recovery was uneventful, until May 1, three weeks after the operation. It seems that on that day his visitors smuggled in a lot of fruit, which he ate. At any rate he began to have severe colic. Laxatives, followed by an enema, moved his bowels slightly, but did not relieve him. Next morning he began to vomit and bowels could not be gotten to move. Condition became progressively worse, Next day, May 3, extreme abdominal distension, fecal vomiting, pulse very bad, at times uncountable, was taken to the operating-room for an exploratory laparotomy.

Under chloroform, followed by ether anæsthesia, abdomen was opened in the median line. The gut was so distended that nothing could be done until it was punctured and relieved of a very large quantity of fecal matter and gas. Gut was sewed up again, and that part of it relieved of its distension by the puncture explored and returned, nothing so far being found to account for the obstruction. The gut, at a distance from the first puncture, was as yet so distended that a second incision in it was necessary to allow of further exploration. This allowed the exit again of a very large quantity of fecal matter and gas, and of a further exploration. The patient's condition becoming extreme, to finish the operation as soon as possible, the second incision in the gut was sewed into the abdominal wound to form a fecal fistula and relieve his intestinal obstruction in this way.

His condition after this operation remained critical for a couple of days, but he rallied and gave us another surprise, when two days after the operation, besides fecal discharge from the fistula, he passed flatus and fecal matter from the rectum in response to a rectal enema. From this time on he began to improve. The only explanation I can find for the obstruction that was the cause of this second operation is that it was a volvulus, or possibly an intussusception, brought on by active peristalsis during the colic caused by the fruit that he ate, and that this volvulus or intussusception was unknowingly reduced during the manipulations of the operation.

Two causes prevented the patient from regaining his strength after the operation, both due to the location of the fecal fistula, which seemed to be very high up in the small intestine. One cause was that the continual discharge from the fistula was of such an irritating character that in spite of everything tried to overcome it, the whole surface of the abdomen and sides became eroded and inflamed, causing continual suffering. The other cause was that though he had appetite and ate, whatever he took came through the fistula, undigested, almost as he took it. This lack of nourishment, in spite of nutritious rectal enemata, brought his general condition so low that he hadn't enough vitality to stand any operative interference to close the fistula. I decided to make an attempt to close it without opening the peritoneum, and on June 2 he had his third operation, under partial chloroform anæsthesia. It consisted in separating the skin from the gut adherent to the deeper structures and sewing up the two layers separately. The peritoneum was opened during the manipulation. This held the fistula closed for four or five days, when it gradually opened again. But the effect of these four or five days' closure of the fistula was wonderful in the difference it made in the condition of the surface, and especially in his general condition. The improvement was so great that I decided to do a laparotomy and resection of that portion of the intestine containing the fistula.

On June 9, under chloroform anæsthesia, he had his fourth operation. Incision again in median line, above and below the fistula, adherent gut gradually separated, though with very great difficulty, and about five inches resected. Ends brought together with a Murphy button, mesentery stitched up, wound closed layer by layer, except a small opening for drainage.

First movement of the bowels two days after the operation. Uneventful recovery. The Murphy button, not having been seen by the 24th day after the operation, *x*-Ray examination was made, but no trace of it could be discovered. It must have been overlooked by some negligent nurse, and thrown away with his stool. On the 27th of July, seven weeks after this operation, he was temporarily discharged to spend a month in Rockaway Sanitarium, before submitting to the last operation for a fecal fistula, due in part to the peculiar situation of his appendix, which I mentioned in the earlier part of this report.

As I said then, the appendix lay almost in front of the cæcum. After its excision the stump presented almost perpendicularly in the wound. This part of the wound was open and packed. As it granulated up the stump of the appendix remained sticking up there in the center of the wound. The complications of intestinal obstruction, etc., coming on, and being of more importance than this condition, it was left alone, with the result that in the contraction and cicatrization of the wound the tip of the stump remained projecting above the surface. About the fifth week after the first operation, it was noticed that some few drops of fecal matter would occasionally come through this stump. A probe inserted, entered the gut. Later on the gut began to prolapse through this small fistula. That is, the central wall of the fistula (mucous surface) would protrude and fold back on itself like a collar, and could be reduced. After all his other troubles were attended to, he was taken to the hospital again on August 27, for his fifth operation. The original incision was reopened, the fistula, practically the elongated stump of the appendix, isolated, the redundant portion of it excised and the edges turned in and sewed over with Lembert sutures. The layers of the abdominal wall were sewed separately above, leaving a small gauze drain in. Prompt and uneventful recovery. Discharged October 1, 1902.

Case III.—Mrs. Ella L., age fifty-six, widow, mother of nine children, youngest now sixteen years old. First she knew of femoral hernia was during an attack of abdominal colic about a year ago. Noticed swellings in both groins, which were both easily reducible till the beginning of her present trouble. On admission to the Beth Israel Hospital, all symptoms of intestinal obstruction and femoral hernia in left groin were present.

Was operated on at once. Incision enlarged upward into abdominal cavity, cutting through Poupart's ligament. About six inches of gut, including the gangrenous portion, was resected, and open ends approximated with Murphy button. Sac removed and wound closed, except sufficient for drainage.

First movement of bowels occurred on the second day. The patient made an uneventful recovery. The button was passed on the seventeenth day. The patient was discharged on September 7.

New York, April 18, 1903.

THE USE OF SALICYLIC ACID AND BORIC ACID AS PRESERVATIVES IN FOOD.

THE question as to whether preservatives should be used in food is one which has been agitating the general public and the medical profession for the past few years. There are some—mainly those who are interested in the matter from a pecuniary standpoint—who aver that certain preservatives are not harmful to health, or if so to such a slight extent that their use is of little consequence. Others contend that preservatives should not be used at all, or when mixed with food, a label should be attached to the compound, indicating the nature and quantity of the preservative. A commission was appointed in Great Britain some time ago to look into the matter, and has recently handed in its report. The commission generally condemned the employment of preservatives in food, and recommended that the law should be altered so as to require manufacturers to state the nature and amount of the preservative, whatever it may be, which is present in certain articles sold. The commission would allow the use of salicylic acid, but would limit it to one grain per pint.

In the *Lancet*, March 14, is an article by Drs. Macalister and Bradshaw who join issue with the findings of the commission, and as the result of experiments made by themselves endeavor to show that the presence of salicylic acid in food, even in comparatively large quantities, has no injurious effect on the health of consumers.

The writers of the article lay down the postulates that salicylic acid is considered injurious to health for the following three principal reasons: (1) That it is an antiseptic and anti fermentative, and is, therefore, liable to interfere with the digestive processes by destroying the digestive ferments; (2) that after absorption it is apt to injure the general health and to interfere with nutrition, and (3) that it is an irritant and is, therefore, apt to injure the mucous membrane of the stomach and intestinal canal. The conclusions which they came to were these: They found—by means of painstaking and exhaustive experiments—that the digestive processes will proceed in the presence of salicylic acid, even in a solution of one in five hundred, which is practically saturated. It was further ascertained that salicylic acid in neutral solutions has absolutely no retarding effect whatever on the conversion of starch by the amylolytic ferment of the pancreatic juice. In short, they found that salicylic acid exerts about the same retarding influence on the digestive processes as do many articles, such as kitchen salt, which are always present in a mixed diet. In order to solve the next problem, viz., the effect of salicylic acid upon nutrition, laboratory experiments being more or less useless, the authors put into practice the only practical method of investigation, that of taking the acid themselves and giving it to others. The result of this experiment also was, that no injury to health seems to have been done. It is pointed out too, that insects do not appear to be harmed by taking salicylic acid dissolved to saturation in syrup. Lastly, with regard to the question whether salicylic acid causes an injury to the gastrointestinal mucosa, the authors write thus: "In the first place it is well known that in the early days of the treatment of acute rheumatism with the salicylicate preparations, large doses of the acid were employed, but no indications of irritant poisoning are recorded. Kolbe, for instance, while directing attention to its strongly antiseptic qualities, states that it is not poisonous to human beings, and in proof of this he himself took and gave to other persons from fifteen to twenty-three grains a day for nine months together, without apparent injury."

Another objection put forward to the use of preservatives, the writers reduce to the form of a syllogism, as follows: Antiseptics kill protoplasm (in bacteria); the human cells are protoplasm. Therefore, antiseptics kill the human cells. And they answer the implication thus: "It might be sufficient to reply that when the antiseptic enters the body it becomes so diluted that its action on the protoplasm of the body would become infinitesimal, but a more complete answer is found by pointing out that there is a fallacy in the assumption that a substance which has a deleterious action on one kind of protoplasm must act detrimentally on all kinds."

The article by Drs. Macalister and Bradshaw is, in a way, a whitewashing of preservatives in food and of salicylic acid in particular. Their experiments go to show, perhaps, that the harmfulness of salicylic acid in food has been exaggerated, but at the same time they do not carry conviction that the food containing it is not more injurious to health than that without. Preservatives, to some extent, may be necessary in food, but the majority of persons will be inclined to think that a limit should be placed on their use, and that the recommendations of the British Commission are based on sound views.

With regard to the use of boric acid as a food preservative, the *Lancet* of March 14 had an apt quotation. Quotation was made from an article contributed by Dr. G. Merkel of Nuremberg to the *Münchener medicinische Wochenschrift*, January 26, in which he refers to the injurious effects of boric acid as an internal medicine, and also as a food preservative. Dr. Merkel is of the opinion that boric acid taken internally in medicinal doses produces irritation of the gastrointestinal tract. His conclusions are founded upon observations made on eleven patients suffering from various slight ailments, but in whom the gastrointestinal tract was normal. The use of the drug is contraindicated, declares Dr. Merkel, in the case of invalids or persons in delicate health. It should not, he thinks, be used as a pre-

servative for milk or "canned" foods. Food "preserved" with it may be taken sparingly by healthy persons, but such food should never, in his opinion, be given to invalids.

The Medical Record has treated the subject more than once editorially, and has championed the cause of those who are against the use of preservatives. There are, undoubtedly, times when canned food cannot be dispensed with, and a certain amount of preserving material must be employed to keep such eatables in condition fit for human consumption. But on the other hand, preservatives are frequently used when not absolutely necessary, and in quantities more or less injurious to health. Despite the assertions made by some that neither salicylic acid nor boric acid are harmful, it would be well if the amount of these drugs as preservatives was strictly limited by law.

THE MICROCOCCUS OF ACUTE RHEUMATISM.

Dr. E. W. Ainley Walker, Gordon Lecturer, Guy's Hospital, London, writes in the *Practitioner*, February, on the infective agent of acute rheumatism. He endeavors to show that one and the same microorganism as is found in rheumatism is obtainable from cases of malignant endocarditis, and from chorea; and, on the other hand, that the organism isolated from a simple rheumatism may produce in animals malignant endocarditis, and probably, at times, chorea also; thus adding to the strong clinical and hygienic evidence that acute rheumatism is an infective disease. Malignant endocarditis terminates a group of cases which, at certain periods of their course, cannot be definitely marked off from acute rheumatism, and these, asserts Dr. Walker, must of necessity be taken into account in a consideration of the etiology of the latter condition. The same remarks apply with less force to chorea.

In the first instance the author argues ably in favor of a single and determinate infective agent being the cause of acute rheumatism, and declares that the "mixed infection" theory has absolutely nothing to support it. After giving a brief history of the result of previous investigations, Dr Walker describes at some length the outcome of researches into the etiology of acute rheumatism undertaken by Dr. Beaton and himself. These workers agree with the opinion expressed by Poynton two years ago, that a particular microorganism, and no other, is constantly associated with acute rheumatic lesions, and is their causal agent. Poynton and Payne have obtained this diplococcus, from some eighteen cases of acute rheumatism, and have by its inoculation produced in animals the following lesions: Polyarthritis, percarditis, myocarditis, endocarditis, pleurisy, nodule formation, fungating endocarditis, with visceral infarctions, and probably chorea. It was with the view of verifying these and similar results arrived at in Europe by other investigators that Drs. Walker and Beaton began an investigation of the bacteriology of acute rheumatism. They have succeeded in obtaining the particular micrococcus from rheumatic patients in fifteen cases, and have examined the action of four different specimens of the organisms in healthy rabbits with positive results Among the cases were eight of acute rheumatism, three cases of chorea, and four of malignant endocarditis in rheumatic subjects.

The organism is described as follows: A tiny micrococcus, which is usually found in ordinary films from artificial cultures, arranged in pairs and chains. When growing in the tissues, as, for example, in a cardiac valve, it shows marked pairing of the elements, but also the arrangement into streptococcal chains; and in artificial culture, in particular media, it can be made to exhibit chains of quite remarkable length. It stains well with ordinary dyes, such as carbol, methylene-blue, carbol, thionin-blue, and fuchsin; and it retains the stain when treated by Gram's method, or, by the Weigert modification of this method, Beaton and Walker grew in the following culture media: bouillon, peptone, water, dextrose, saccharose, glycerin, lead and nitrate bouillon, gelatin (stab, streak, and shake), agar-agar, glycerin-agar and blood-agar, blood-serum, milk, and potato. In their opinion it is in culture indistinguishable from an ordinary streptococcus. It forms a considerable amount of acid, no gas, no indol, no hydrogen sulphide, and no nitrites in nitrate media. It grows anaerobically as well as in aerobic culture. On potato there is no visible growth, but growth takes place in cultures made in sterile urine.

Upon the question as to whether this organism is an ordinary streptococcus or specific, hangs the whole argument for the specificity of rheumatism. Gustav Singer holds that the infection of rheumatism is caused by an attenuated streptococcic septicæmia.

The only way in which specificity can be established, is by the discovery of some characteristic difference in either the microorganism or its products sufficient to distinguish it with certainty from the other members of the "streptococcus" group. No differences of this kind have as yet been found.

Dr. Walker considers that the points which urgently demand investigation are these: First and foremost, the question of specificity, and when the bacterial specificity of rheumatism has been accepted, the problem of its toxic specificity must be attacked.

So far as the investigations in regard to the microorganism of acute rheumatism are concerned, they may be said to have been attended with a fair measure of success, and to warrant to a large extent the opinion of Dr. Walker that acute rheumatism is caused by a specific infective agent. Until, however, the organism can be distinguished from an ordinary pyogenetic streptococcus, the matter must remain unsettled with, perhaps, a leaning toward the views so eloquently advocated by Dr. Walker.

THE LIVER TEST FOR SUDDEN DEATH.

In the *Wiener klinische Wochenschrift* for February 26, 1903, Prof. J. Seegen criticises Martin and Lacassagne's test for sudden death based upon the condition of the liver as regards the absence of sugar and glycogen, the presence of sugar and glycogen, or the presence of sugar with absence of glycogen. The absence of sugar and glycogen Martin and Lacassagne consider evidence of death preceded by

a long agony; the presence of sugar without glycogen, evidence that a disease was cut short by a sudden, intercurrent cause; and the presence of both substances, evidence that death occurred without preceding disease. If this test be reliable, its importance for legal medicine is evident. Martin and Lacassagne direct that a piece of finely cut liver be boiled a short time and the decoction mixed with animal charcoal and filtered. Milkiness of the filtrate betokens the presence of glycogen; a clear filtrate, its absence; precipitation on heating the filtrate with Fehling's solution, the presence of sugar. Seegen criticises this method, which has some appearance of a "while you wait" process. In particular, the charcoal can extract sugar from the solution, and, indeed, Modica, by omitting the charcoal and by using the phenilhydrazin test, reached conclusions different from those of Martin and Lacassagne; and, further, Verwaeck obtained very different results in two series of cases, in one of which he used Martin and Lacassagne's, and in the other, Modica's method. Strohe also obtained results similar to those of Modica and Verwaeck, while Brown and Johnston, using the method of Martin and Lacassagne, confirmed the results obtained by them. By more refined chemical methods Seegen found in one case of death from asphyxia, one of death from carbon monoxide poisoning, and one in which death probably occurred from asphyxia after breathing of carbon monoxide, both sugar and glycogen present invariable amounts. He also found those substances in large amount in the liver of a dog killed suddenly after one hour of asphyxiation, and in that of two others dying after six hours of asphyxiation, but in one of the last cases the glycogen was present only in traces. Seegen concludes that, on the basis of physiological considerations to which the findings of Modica, of Verwaeck, and of others are entirely conformable, and upon the important results ascertained in the cases of asphyxiated individuals, the conclusions of Martin and Lacassagne do not correspond to the facts and are not justified. It is, on the whole, true that in healthy individuals dying suddenly the liver in most cases contain sugar and glycogen in abundance, and that in cases of individuals dying of disease the amount of the substances named is diminished; but from these facts, which hold only within wide limits, it is entirely unjustifiable to draw an "indubitable proof" that death was slow or sudden.

The Widespread Increase of the Cocaine Habit.

A grand jury recently sitting in Chicago, for the purpose of probing into the question of the sale of dangerous drugs, came to some rather alarming conclusions. Representatives of the Illinois State Board of Pharmacy had testified that in their opinion the sale of dangerous drugs was carried on in Illinois, and especially in Chicago, to a large extent. The grand jury confirmed these opinions and declared, in its final report, that there was an alarming growth in the sale and use of cocaine. Druggists in Chicago and in other parts of the State of Illinois were known to dispense the drug without a physician's certificate, and the grand jury recommended that legislation and police activity should be evoked to break up the dangerous practice.

The London *Speaker*, commenting upon the same matter, says, "Even the most casual of newspaper readers must have noticed how many have been the cases of cocaine poisoning during the past few years. Either the drug has been prescribed in the first instance by a physician, or, what is more common, has been an ingredient in some patent medicine, to relieve nerve pain. Its value as a local anæsthetic, and its immediate tonic effect upon the nervous system, are so marked that the patient grows more and more to depend on it for relief. The cocaine habit is induced, and the victim soon becomes a physical and mental wreck. The dangers attaching to the indiscriminate use of the alkaloid of the cocoa plant and its fascination for neurotic subjects are now well recognized among physicians of repute; but it forms a too-frequent constituent in many popular medicines, for it is a cheap drug, and, unhappily, there are—at least so far as America is concerned—no restrictions or laws regulating its sale."

The cocaine habit is undoubtedly on the increase, and is more prevalent in this country than anywhere else. The American, by incessant work and by the continued strain on the nervous system necessitated thereby, frequently finds himself run down and suffering from dyspepsia, neuralgia, and various other ills and pains—symptoms that the body is rebelling against its abuse. Instead of endeavoring to recuperate by rational, sane methods the sufferer drugs himself into insensibility by means of drugs, such as cocaine. He does not understand that pain and lassitude are merely the red flags hung out by nature to show that there is danger ahead, and that to resort to drugs to bring forgetfulness or to deaden pain is to run counter to the dictates of commonsense. Laws are needed everywhere to restrict the sale of dangerous drugs and of patent medicines containing the same, so that temptation may not be placed in the way of the perverse and neurotic inhabitants of this and other lands.

Laboratory Diagnosis and the General Practitioner.

Dr. B. M. Randolph, Jr., Dean of the Philadelphia Polyclinic, contributed to the *Old Dominion Journal of Medicine and Surgery*, January, 1903, an article on the above subject. The writer argues that the general practitioner can and should make use of laboratory methods for diagnostic purposes. The medical man in general practice is too apt to regard such work as lying out of his province, and belonging to that of the worker in the clinical laboratory.

Dr. Randolph, however, asserts that the general practitioner with a microscope, a small quantity of apparatus, and a few reagents and stains can do nearly all the essential diagnostic work, and do it without the expenditure of a great amount of time. Of course there are many tests which cannot be undertaken unless elaborate apparatus is at hand, and which require close attention and much time. The first need for most of the tests that are of positive value and constantly in demand, says Dr. Randolph, is an ordinary physician's microscope. A table two by four feet, having a small drawer, will give ample room and place for all necessary stains, reagents, and apparatus. Half a dozen stains, the ordinary simple chemical reagents, and a few special mixtures will make up the complement. With these the physician can examine urine, sputum, blood, pus, exudates, fæces, stomach contents, and obtain much valuable information.

Indeed, there are few diseases or conditions which cannot be tested and valuable aid afforded by making a diagnosis by these means.

There is no doubt that the clinician is becoming

more and more dependent on the laboratory, and, as Dr. Randolph truly says, "No man can afford to ignore the question of equipping himself to do clinical microscopy and chemistry unless he is so situated that he can have such work done for him. Competition is keen and getting keener, and the standard of medical attainment is becoming too high for any physician to fail to make use of every aid to diagnosis possible."

Toxæmias from Spirit Drinking.

Although there is yet much difference of opinion as to the action of alcohol on the human system, the preponderance of evidence goes to show that the value of the spirit either as a food or as a therapeutic agent is very limited. It is agreed on all hands that drinking to excess is extremely harmful.

Dr. T. D. Crothers, who is, of course, strongly opposed to spirit drinking in any form whatever, and who is one of the most earnest advocates of strict temperance in this country, contributed an article dealing with the matter to the *Albany Medical Annals*, January. He holds that many of the complaints from which persons frequently suffer and termed bilious, malarial, or rheumatic, characterized by dull pain, slight fever with general exhaustion, and wandering neuralgias and myalgias, are simply toxæmias from spirit drinking. Dr. Crothers' conclusions are as follows: (1) Alcohol in any form, taken into the body as a beverage, is not only a poison, but produces other poisons, and associated with other substances may develop toxins. Alcohol is also an anæsthetic and not a tonic, or so-called stimulant. It increases the waste products of the body and diminishes the power of elimination. It also destroys the phagocytes of the blood, and thus removes and lessens the protective power of the blood cells. (2) Whenever alcohol is used continuously as a beverage for its medicinal effects, favorable conditions and soils for the cultivation of and growth of poisonous compounds are created. These may be neutralized by other conditions, and not be apparent in the derangements of the functional activities which follow. When disturbance and derangements of the nutrient and functional activities of the body are associated with the use of alcohol, their transient character and disappearance by the removal of spirits suggest the causes. (3) The functional and organic symptoms of derangement appearing in those who use spirits in moderation or excess, which quickly disappear by abstinence and eliminative measures, are clear indications of autointoxications from this source. Obscure symptoms of the nervous system in persons who use spirits should always be examined in relation to the toxic origin from this source. Also grave nutrient disturbances should suggest the same cause with the same treatment. (4) The treatment of all such cases, in which alcohol is used in any form, should be by antiseptic and eliminative measures, and the supposition should always include the possibility of poison by chemical products formed in the body.

Trachoma in the United States and in Egypt.

The *Practitioner*, February, contains an article by Mr. E. Treacher Collins, F.R.C.S., one of the best known British authorities on ophthalmology, entitled "A Review of Recent Work on Ophthalmology," the greater part of which is taken up with a consideration of trachoma and the methods for the prevention of its spread. Mr. Collins highly eulogizes the measures taken in this country for preventing the dissemination of trachoma, and quotes extensively from the *Boston Medical and Surgical Journal* and the Medical Record to show that the enforcement of the law prohibiting the entrance of immigrants afflicted with trachoma, and the passage of "The Act for the Better Preservation of the Health of Children in Institutions" by the New York Legislature in 1886 have greatly lessened the prevalence of trachoma in the United States. With regard to the article on the subject by Dr. Derby, in the Medical Record, of July 5, 1902, it is noted that the writer in question complained that at the present time there is no hospital in New York City adequate for the reception and care of all cases that would be found by school inspection, though fifteen years ago he advocated the erection of such a building.

As to the prevalence of granular ophthalmia in Egypt, Dr. Collins contrasts the active measures being taken here to check its spread with the sad description which MM. Morax and Lakah give of the affection in Egypt, where for ages practically nothing has been done to limit its spread. Their paper is entitled "Clinical Investigations on the Etiology of Trachoma in Egypt," and is published in the *Annales d'Oculistique*, November, 1901. After stating that in Egypt it is quite the exception to find a native who, when the lids are everted, does not show signs of either past or active trachoma, they proceed to demonstrate that it is in childhood that the infection is most frequently contracted. MM. Morax and Lakah examined ninety-five foundlings and orphans at an institution, whom they divide into two series: (1) The older children between twelve and seventeen years of age comprising more orphans than foundlings; of twenty of these, seven presented typical granulations, thirteen had no conjunctival disease. (2) Children between twelve and two years of age; of seventy-five of these, fifty-six had granular ophthalmia. The average number of cases of granular ophthalmia among the children in several native schools which they examined was 93 per cent.

As a result of their observations, the authors do not think that climatic conditions or race have any influence in the development of the disease. Dr. Alfred Osborne, however, who has had five years experience in a large polyclinic in Alexandria, in an article "On the Relation of Epidemic Conjunctivitis in Egypt to Climatic Conditions," in the *Archiv für Augenheilkunst*, Vol. XLIV, No. 2, says that the increase in eye diseases in the hot months from April to August or September follows a curve approximately like that of all the plagues of Egypt—light, heat, dust, the overflow of the Nile, and flies.

The Diseases of Organic Demineralization; Plasmatic Anæmia.

In the *Bulletin Général de Thérapeutique* for December 23 and 30, 1902, Dr. Albert Robin calls attention to a nutritive disturbance of the highest importance which appears to have escaped attention hitherto. Gaube has shown that each tissue has its dominant mineral, which plays a very significant rôle in the nutritive processes of that tissue. If one endeavors to ascertain the relation which exists in a healthy man between the mineral components and the total residue of the urine, it is found that the figures vary within narrow limits, from 28 to 33 per cent. of the total dry residue, the average (the coefficient of demineralization) being 30 per cent. A study from this point of view of numerous cases has led Robin to the following conclusions: A group of morbid states exists, which have as one of their conditions, if not of their causes, either a demineralization of

the organism, or an inaptitude of the plasma and of the tissues for fixing the inorganic principles of the food. Among these diseases Robin's studies enable him to indicate the following types as the first terms of the series, namely, phthisis pulmonalis, chronic phosphorus poisoning, a special variety of hæmoglobinuria, various albuminurias (such as the phosphaturic and the dyspeptic), which, at first functional, can end in Bright's disease; and an important group of anæmias, certain of which present all the clinical appearances of chlorosis. The last is not a morbid entity, but certainly a symptomatic *ensemble*, which depends upon very dissimilar morbid conditions, and requires altogether different treatments, inasmuch as it is necessary to treat the morbid processes which end in the chlorosis or anæmia rather than the symptomatic expression of them. Organic demineralization is one of these processes. The chlorotic and anæmic victims of it show certain clinical peculiarities which lead one to suspect its presence, but to render the diagnosis certain it is necessary to undertake a comparative analysis of the urine and of the blood. The demineralization is proved by an increase in the mineral residue of the urine and of the coefficient of demineralization, and by a correlative decrease in the mineralization of the blood. The analysis shows that this demineralization affects the blood plasma, the saline equilibrium of which is broken, and as an immediate result we have either an alteration of the red corpuscles, or a retardation in their renewal, or a diminution of their activity. In fact, in a typical case, the number of red corpuscles fell to 2,329,000, with a globular value of 72 per cent. This variety of anæmia then deserves the name of plasmatic anæmia. In order to treat and to cure it in a, so to speak, mathematical manner, it is necessary to restore the saline equilibrium of the plasma, a result which is attained rather rapidly by the use of a combination of the salts of the blood with different organic principles. This mineral reconstitution of the plasma requires from fifteen to fifty days, according to the case. It shows itself by an increase in the mineralization of the blood and by a diminution of in the inorganic residue of the urine, in spite of the daily ingestion of the mineral salts. When the saline equilibrium of the plasma is reëstablished it is proper, as a second therapeutic step, to institute a course of iron, which then acts with a surprising rapidity on the external signs of the chlorosis. One may, however, associate the iron directly with the saline medication. The diagnostics and the treatment of plasmatic anæmia furnish a proof of the certainty of therapeutic measures when these are founded upon the exact processes of pathological chemistry.

Quinine and Malaria.

Dr. Cartaz, a French physician, discusses in *La Nature* (Paris), February 7, and quoted in the *Literary Digest*, the question as to how quinine acts in malaria. Dr. King, an American physician, has advanced the argument that the property of fluorescence which quinine possesses, is probably one of the causes of its ability to destroy the malarial parasite. The argument is somewhat as follows: Malaria is due to the presence of a parasite in the blood; it has been discovered that this parasite gains access to the human body by means of the bite of an infected mosquito. The parasite of malaria scarcely ever develops except in darkness. Is it the red color of the blood that favors its life and the violet rays that interfere with its evolution? According to Dr. King, quinine is a fluorescent substance, and it is through this fluorescence that it acts as a destroyer of the malarial parasite. Dr. King points out that two vegetable substances, already employed as remedies for malaria, esculin and fraxin, the active principles of the horsechestnut and the ash, give blue rays. Iodine, which is not fluorescent, finds in the system starchy substances with which it combines to form an intensely violet-blue combination. Methylene blue, recently prescribed in forms of chronic malaria, and in inveterate neuralgia, would also act by emission of rays hurtful to the parasite. Again, it has been long recognized that the absorption of quinine increased the fluorescence of the blood, and that this is lessened or increased, according to the doses prescribed, and to the lapse of time since the ingestion of the salt. The parasite, then, like many microbian agents, must be disagreeably influenced by the violet rays. Dr. King admits that there are cases of malaria that resist quinine salts, but then, he asserts, the attacks are due to the undeveloped and not to the complete parasite. The undeveloped parasite is bound especially in the deep organs, and the more obscure parts of the body. Under these conditions the destructive action of quinine cannot take place, for its fluorescent power is then nearly absent.

Dr. King's theory is an ingenious one and, furthermore, sounds plausible. Until the cause of malaria was known it was impossible to discuss the manner in which quinine exerted its influence upon the malady. Now, however, that the secret of the origin of malaria has been cleared up, the question of how quinine acts comes within the province of practical research.

A Model Sanatorium for Consumptives.

Dr. Arthur Latham, the winner of the first prize in the competition for the best essay as to how the sanatorium for the treatment of indigent consumptives in Great Britain, given by Sir Ernest Cassel, should be built and managed, gives some useful advice on these points. He first draws attention to the fact that the accepted methods of treating tuberculosis are by no means new, but were laid down by English physicians a century ago. English physicians then believed in the efficacy of unreserved exposure to fresh air for consumptives, and they also recognized the importance of a scientifically regulated diet. But these men were in advance of the times, and were generally regarded as mad enthusiasts whose teachings if carried into practice would soon result in death to their patients.

Dr. Latham does not believe that altitude affects to any appreciable degree the microbe of tuberculosis. Be the situation high or low the organism is destructive if other conditions favor its activity. The surest safeguard against infection is to be in a perfect state of health. When the vitality is lowered by any cause, there is danger of infection. The victim of phthisis should be removed as quickly as possible to an open air sanatorium.

The following is a description of what Dr. Latham thinks an ideal sanatorium: (1) The buildings are so situated and of such a nature that the formation of all dust is, as far as possible, avoided. (2) The dust which inevitably collects can be readily removed. (3) All infected material can be readily and effectually destroyed or disinfected. (4) The atmosphere of the building is free from all source of contamination and rivals the outside air in point of purity. (5) The number of recreation rooms and other places of assemblage is limited and everything avoided which is calculated to tempt patients to stay indoors. Dr. Latham further lays down these rules: (1) The bedrooms of the individual sexes should, as far as possible, be in separate blocks. (2) The accommodation for visitors should be strictly limited. (3) No special provisions should be made

for exciting amusements, but a well-stocked library and other forms of harmless recreation should be provided. (4) The means of heating employed should be easily regulated and of such a kind that they do not interfere with the humidity of the air. (5) Although there must be free circulation, draught should not be encouraged. (6) Efficient shelter should be provided against wind, sun, and heavy rain, not only in the sanatorium itself, but in the grounds.

News of the Week.

Medical Practice Act for New Jersey.—The State Board of Medical Examiners of New Jersey has secured amendments to the Medical Practice Act of that State by which the academic standards for admission to the State examinations have been raised from a competent common-school education to a diploma issued after four years of study in a normal, manual training, or high school of the first grade in that State, or its equivalent. The medical requirements have been increased from three to four courses of medical lectures of at least seven months each, in different calendar years, prior to receiving the degree of Doctor of Medicine. The amendments go into effect on July 4 next. After that date candidates for examination, or for the endorsement of a license issued by a recognized examining board of another State, will be obliged to comply with the new standard of requirements for a New Jersey license.

State and County Civil-service Examinations.—The next general examinations for the State and county service will be held on May 9, 1903. The following positions are included: apothecary, trained nurse, library assistant in State library, clerk and statistician in department of labor. Applications will also be received for medical interne in State hospitals and institutions. Application blanks and information regarding salaries and requirements of examinations may be obtained by addressing the Chief Examiner of the Commission at Albany.

A Preliminary Note on a New Nitrous Oxide and Ether Inhaler.—The apparatus is designed to give air, then gas, and finally ether to the patient, with the minimum of inconvenience and the maximum of speed in anæsthesia; and to be operated with one hand, leaving the other free. It consists of a metal cone, shaped much like the conventional one, with a compartment above for ether, and below a mixing chamber or face portion. On the side, and conveniently operated by three fingers, are three sliding valves for the ingress of air, gas, or ether, as required.—Nathan W. Green, M.D., Assistant Surgeon, Roosevelt Hospital, O. P. D.

Dr. Paul Garnault Here.—Dr. Paul Garnault arrived in New York on April 11. Dr. Garnault, it will be remembered, attempted to prove the fallacy of Koch's assertion that bovine tuberculosis could not be transmitted to man, by a practical experiment upon himself. The Parisian physician caused himself to be inoculated with the bacilli of tuberculosis in June last, and claims that he became locally infected with the disease.

Proposed Congress on Consumption in New York City.—Dr. Robert Taylor, according to the New York *Tribune*, has written a letter to Mayor Low suggesting an American Consumption congress. In the course of his letter he says: "In such a cause as the present popular war waged against pulmonary tuberculosis, all who have real scientific knowledge of successfully tested preventives or remedies should contribute that knowledge for the general welfare. What should be—and the time is right and ripe—is to call and organize in New York an American consumption congress. To this national convention the delegates should include general medical practitioners and specialists, bacteriologists, microscopists, sociological experts, persons with hospital and sanatorium experience, representatives of charities and municipalities, and all whose testimony or advice could aid in arriving at the truth, and the best plans for a grand campaign for the victorious rescue of all humanity throughout the world from consumption."

Mumps at Columbia College.—There is a small epidemic of mumps at Columbia College. A dozen or more students have been affected, most of whom were in the Law School.

Music as a Therapeutic Agent.—The Society for the Culture of Musical Therapeutics has been inaugurated under the patronage of Dr. Egbert Guernsey. Miss Augusta Viscelius will deliver a series of lectures on the relation of music to medicine. The first is to be given at Dr. Guernsey's apartments, the subject being "History of Music as a Healing Power." Other lectures will be "The Musical Gift; How to Develop It for Healing," and "Choice of Songs and Instruments in Healing."

Sanatarium for Actors.—It is intimated, says the New York *Tribune*, that on or about May 1, a committee of doctors will decide on a place for the proposed sanatorium for consumptive actors, and that the work of building it will then be started. Mr. Robert E. Bell of Denver, who planned this scheme, has organized an executive committee to carry on the work—comprising the Rev. Walter Bentley of the Actors' Church Alliance, chairman; Mrs. Eldridge of the Woman's League, Albert Borie of the *New York Clipper*, Charles Burnham of Wallack's Theatre, and Peter McCourt of Denver. Benefit performances, beginning about April 20, are to be given in New York, Chicago, Philadelphia, Boston, St. Louis, Denver, and other cities. Many actors and managers have promised to coöperate in the work, and it is expected that a fund of at least $75,000 will be accumulated in a short time.

Powers of Boards of Health.—A decision has just been handed down by the Appellate Court which is of interest to boards of health. A man by name of Van Fredenburg collected refuse and garbage from hotels and other resorts in and near Liberty, N. Y. with which he fed hogs. The Board of Health of Liberty issued an order forbidding him to use the sanatorium refuse. On his refusal to comply with the order, he was arrested, brought before a justice, tried in the County Court, convicted and sentenced. Van Fredenburg appealed, and the Appelate Court in reversing the judgment, laid down the principle that boards of health must keep within legal limits or they cannot enforce their orders. The Court summed up as follows: "The gist of the crime which the defendant is said to have committed is the disobedience of a lawful order of the Board of Health. Unless, then, the order disobeyed was one lawfully made by the Board of Health, defendant had been guilty of no crime. There is no proof that this refuse from the sanatorium for consumptives is any more dangerous than the refuse from any hotel, and we cannot assume such to be the fact in sustaining this conviction."

Lectures to State Alienists.—Dr. Adolf Meyer, director of the Pathological Institute of the New York State Hospitals on Ward's Island, has reported to the Commission in Lunacy that he has just finished the third course of instruction to the physicians of the fourteen State hospitals. These three courses of lectures and clinics have been given

by himself and his assistants at Ward's Island during the past winter. Sixty-one physicians belonging to the staffs of the State Hospitals at Buffalo, Utica, Gowanda, Middletown, Rochester, Ogdensburg, Poughkeepsie, Brooklyn, Central Islip, Kings Park, Matteawan, Dannemora, and New York have attended the three sessions.

The Late Prof. T. Gaillard Thomas.—At a meeting of the Medical Association of the Greater City of New York, held on April 13, 1903, a committee on the death of Dr. T. Gaillard Thomas presented an elaborate sketch of the distinguished career and eminent services of Dr. Thomas. The conclusion of the report was as follows: "In the death of Dr. Theodore Gaillard Thomas this society recognizes the loss of one of its most distinguished and most valued members. Its memory of Dr. Thomas will be of a man of keen intelligence, wide cultivation and accomplished skill; a man of purity of character, broad humanity, and strictest honor."

(Signed) HENRY FREEMAN WALKER,
EDWIN B. CRAGIN,
S. BEACH JONES,
} Committee.

Reduction of the Salary of State Medical Inspector.—Governor Odell has caused J. B. Conkling's bill providing for a State medical inspector for the State insane hospitals to be amended so that the salary will be $3,500 yearly instead of $5,000 and expenses.

Pupils of Catholic Schools Exempt from Vaccination.—Attorney-General Cunneen has come to the decision that the State health law does not compel the authorities of parochial schools to exclude unvaccinated children from attendance, but that the local board of health may, if it deems it necessary, issue an ordinance directing general vaccination and placing a penalty for non-compliance. The issue arose in Dunkirk through a fight on the question of vaccination between the local and State health officials and the Dunkirk parochial schools. An order was made some time ago, excluding a large number of non-vaccinated pupils from the public schools, many of whom entered the parochial schools. Those at the head of these latter schools refused to comply with the law, the result being an appeal to the State board, and thence to Attorney-General Cuneen. It is the first time the matter has been passed upon.

Diseased Beef Sent to New York.—From information received State Agricultural Commissioner Wieting ordered to be seized a carload of cattle shipped from Newport, Herkimer County, to New York. The report of officers of the State Agricultural Department states that a post-mortem examination of the cattle showed that the beasts were badly diseased and wholly unfit for human consumption. The Commissioner intends to have the case followed, and the shipper of the cattle prosecuted if possible.

Rabies Prevalent in New York.—Owing to the number of cases of hydrophobia which have occurred in New York within the past few years, it is proposed that a new system, or a more efficient manner of carrying out the present law, shall be initiated in the city. The duty of keeping the streets free from stray dogs lies with the Society for the Prevention of Cruelty to Animals, and it is asserted that the society is lax in fulfilling this function. There is no motive to look after ownerless dogs, as no fine can be inflicted, and the society, in the case of the owner of a stray dog without a license, caught by its agents, being fined, receives a portion of the fine. All stray dogs should be carefully looked after, as such animals are the chief means of spreading rabies.

Charbon Attacks Human Beings in Louisiana.—In the parish of Acadia, Louisiana, some 225 head of cattle have died recently from charbon. The farmers, ignorant of the infectious nature of the disease, skinned some of the dead animals and sold their skins. As a result thirteen human beings have contracted charbon. The police jury of Acadia has been called together to take steps to stamp out the disease.

Philadelphia County Medical Society.—At a stated meeting, held April 8, Dr. Barton Cooke Hirst read a paper entitled "The Surgical Treatment of Pruritus Vulvæ; with the Report of a Case Cured by Resection of the Genito-Crural Ilio-inguinal, Inferior Pudendal and Superficial Perineal Nerves." The patient had suffered greatly for several years, despite the employment of a large number of therapeutic measures in the hands of many physicians. Six weeks had elapsed since the performance of the operation without return of the symptoms previously present. Dr. Wm. S. Wadsworth presented a communication entitled "Some Reflections on the Causes of Sudden Death," in which he referred especially to the influence upon the heart of various factors, particularly of a toxic nature.

Pathological Society of Philadelphia.—At a stated meeting, held April 9, Dr. F. S. Pearce reported a case of hemiplegia with tuberculoma and extreme atrophy of the right cerebrum." The lungs were the seat of tuberculosis and the cerebral vessels were atheromatous, the right middle cerebral being occluded by a thrombus. Dr. M. H. Fussell exhibited specimens from a case of interstitial nephritis. In the failure to discover tube-casts in the urine the case was clinically believed to be one of hyperæmia of the kidneys secondary to disease of the heart, but the occurrence of uræmic convulsions corrected this misapprehension, and the post-mortem examination disclosed the lesions of contracted kidney. Dr. Fussell exhibited also a specimen of carcinoma of the œsophagus and the stomach. The patient was an old man, aged seventy-three years, who presented symptoms of œsophageal obstruction which eventually became impermeable. Gastrostomy was performed and the patient lived for several months, suffering during this time greatly from thirst. After death, in addition to the new formation in the œsophagus, a large neoplasm was found in the stomach, and which was believed to be secondary to the œsophageal growth. All of the other organs were free. Dr. W. M. L. Coplin presented a communication entitled "Myositis Ossificans," and showed sections of tissue removed from a patient in whom the muscle at the site of a traumatism of the thigh had undergone ossification. Dr. George M. Mueller exhibited a series of card-specimens, comprising dilatation of the heart, with nephritis, perforating ulcer of the duodenum with abscess-formation beneath the liver, perforating ulcer of the stomach with fatal peritonitis, carcinoma of the cervix of the uterus, a dermoid cyst of the pelvis. Dr. C. L. Kieffer exhibited a portion of intestine showing ankylostoma *in situ*, and also a series of specimens illustrating the varied lesions of tropical dysentery of both bacillary and amœbic origin.

Department of Public Health and Charities for Philadelphia.—The Pennsylvania Legislature has passed, and the Governor has signed, a bill establishing in the city of Philadelphia a department of public health and charities to be under the charge of a director and an assistant director appointed by the Mayor of the city and entrusted with the care, maintenance, administration, and supervision of the public health, charities, almshouses, hospi-

tals, and other similar institutions under the control or government of the city. The director shall have the appointment, supervision, and control of all of the subordinate officers and employees attached to the department and the appointment of all vaccine physicians and health-inspectors. He shall also have immediate care and supervision of all hospitals belonging to the municipality in which provision is made for the care of contagious diseases.

To Encourage Large Families.—Alderman Jonathan Buxton of Chicago, in pursuance of the policy to avert "race suicide," will introduce into the Council an ordinance subjecting to a fine of $100 every landlord who rejects a tenant on account of children in his family. But, as a concession to people with "nerves," Alderman Buxton shows how the landlord can escape prosecution. If he can establish the fact that the children of the tenant's family are boisterous and likely to disturb the quiet of the apartment building or flat, he may reject them.

Obituary Notes.—Dr. William A. Durrie of East Orange died on April 8, aged eighty years. He practised in Jersey City before moving to East Orange, but had been out of active practice for many years.

Dr. Guy Bryan Miller, late house physician to St. Luke's Hospital, died on April 7 in Paris, in his thirty-first year. Dr. Miller was a graduate of Yale University and of the College of Physicians and Surgeons in 1898.

Dr. William S. Whitwells of 37 West Eleventh street, died of Bright's disease at Fishkill Landing on April 8. He was fifty-seven years of age.

Dr. Chauncey Ayres died on April 14 at Stamford, Conn., aged ninety four years. He was born in New Canaan, Conn., on August 14, 1808. He was the oldest graduate of the Yale Medical School. He was in the class of 1831. After graduating he began the practice of his profession in Greenwich, but soon went to New York, and was one of the physicians in charge of the cholera hospital during the epidemic in that city in 1832. He was the surgeon of the United States Coast Survey. Dr. Ayres was a resident of Stamford for sixty-four years, and held the office of borough clerk when a young man.

Dr. Frederick Nehrbas died on April 14 at 190 Clarkson Street Flatbush. He was formerly on the medical staff of the King's Park and Flatbush hospitals.

Dr. Albert Huntington Chester, professor of chemistry and mineralogy in Rutgers College, died on April 13 of heart disease. He was for several years connected with the New York State Board of Health as chemist.

The Identity of Human and Avian Diphtheria.—F. C. Harrison states that, from the evidence adduced in literature, from the isolation of the causal organisms (the roup bacillus and the bacillus pyocyaneus), and the production of typical fowl diphtheria by the inoculation of cultures of both of these bacteria into healthy birds, it is evident that the theory of the identity of human and avian diphtheria is unsound. He is unable to state the possible danger of the roup bacillus to man; but we know that the bacillus pyocyaneus produces abscesses and occasionally gives rise to an epidemic of blood poisoning, but neither of these bacteria has the same pathogenic power as human diphtheria.—*Dominion Medical Monthly*, March, 1903.

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent.)

HOSPITAL REMOVALS—ST. GEORGE'S—DEBATE ON DIABETES AND GLYCOSURIA—ARSENICAL POISONING—THE LATE DR. MACLAGAN—CHARGE AGAINST A HEALTH AUTHORITY—THE REGISTERS.

London, March 27, 1903.

"Great alterations and improvements, involving a large expenditure, are necessary to bring the hospital up to the requirements of modern medical and surgical science." These words—probably true of all the hospitals—were used by Mr. Timothy Holmes when presiding at the meeting of the Governors of St. George's. He and others were in favor of purchasing four houses close by, now available, in order to carry out additions. Most of the staff seemed desirous to sell the present site and buy a larger one, on which to build an enlarged new hospital, and the meeting accepted this plan by fifty-one to thirty-two votes, and appointed a committee to negotiate. It seems a pity to sacrifice the finest position in London, and the hospital which was large enough for John Hunter, merely to gratify the craving of the staff for more beds. The hospital is big enough for its proper work; contains 356 beds, according to the school prospectus—and, of course, it can be improved and brought up to date. But all the hospitals are boasting of their size, and the demand on their beds, and their innumerable patients. Their rivalry leads them to desire enlargement, and this, again, appeals to the charitable public. The appeal is further enforced by the cry that everything must be brought up to date, as if this could not be done just as well for 300 as for 600 beds. Another representation of the advocates of removal of several hospitals, is their unequal distribution among the population. There is something to be said on both sides of this question. With reference to St. George's, one point is of special significance. To remove is to throw away a site which it is impossible to match, which also is big enough for its work. If Fulham wants hospital accommodation, a small one could be built there. In fact, it would probably, in all cases, be better to provide more hospitals—of say 100 or 200 beds—in localities needing them, than to agglomerate enormous numbers of patients in one building. But that plan would not gratify the pride of managers.

The Chelsea Clinical Society holds a set debate once a year on some important subject, and usually manages to get some of our leaders to take part in it. This year the subject of the debate was diabetic and non-diabetic glycosuria, and Dr. Hale White of Guys opened the discussion, which extended over two evenings. He commented on most of the points on which we are in need of more information, and asked many questions, concluding with the important one whether under the word diabetes we do not describe more than one disease, *e.g.* are some cases due to disease of the pancreas and some not? Are those that have so-called fatty blood different from those that have not? are those in which glycogen is present in the liver different from those in which it is absent? Among the other things that we want to know Dr. White specified information about the occurrence of other sugars than dextrose in the urine, especially lævulose, lactose, and pentose, and suggested that when we know we might speak of dextrosuria, lævulosuria, lactosuria, and pentosuria. He also asked for a more accurate use of the word diabetes. The addition of the word mellitus does not help, for many speak of alimentary glycosuria as diabetes mellitus, so that hearing a patient has diabetes does not tell whether he has the comparatively harmless alimentary glycosuria or the dangerous one in which he is liable to coma, and passes oxybutyric acid and its derivatives. If we cannot now restrict the word diabetes to the severer disease, we might, perhaps, adopt Dr. Pavy's phrase, "composite diabetes," for cases passing oxybutyric acid and its derivatives, of which aceto-acetic acid is recognized by the ferric-chloride reaction. The detection of acetone is less important, as it is sometimes present in cases which are not diabetes. No case of glycosuria has been properly examined until the ferric chloride test has been applied.

Dr. White thinks that many patients with alimentary glycosuria are really in the early stage of the graver disease, though others never pass into the composite form and so do not exhibit its serious metabolic phenomena. He mentioned the fact pointed out by Pavy many years ago that a patient on strict diet may, if only a little carbohydrate is taken, excrete more sugar than that ingested. No explanation of carbohydrate metabolism in diabetes is satisfactory, unless it accounts for this. The same may be said of the strange disappearance of sugar when coma comes on.

Passing over some other interesting points I will give you some of Dr. White's remarks on treatment. Of course, he puts diet first. We must forbid carbohydrates, for without them patients gain weight and strength, while sugar and oxbutyric acid decrease. But dieting may be too strict. Milk may often be given. Just as much carbohydrate may be allowed as will not increase the sugar. Lævulose is best for this. Inulin may be given in dahlia tubers cooked like potatoes. It is a pernicious error that toast may be taken instead of bread. Many cases do not take enough fat. Large dose of alkalies seem best for coma—100 gr. of sodii bicarbonate dissolved in a pint of milk may be given when a patient feels drowsy, and repeated three or four times in twenty-four hours. Such a dose may be given in a severe case with abundant ferric-chloride reaction and no coma. Codeine, like morphine, will diminish sugar but seems less trusted than formerly. Aspirin has been reported to be useful. This salicylate will give a ferric-chloride reaction—a fact to remember. Dr. White had tried feeding on pancreas and injection of liquor pancreatic us without effect. Professor Starling's secretion seemed also of no benefit in diabetes.

Dr. Pavy defined diabetes as "a more or less persistent defective assimilative power over the carbohydrates of food, resulting in glycosuria." To decide if a case were diabetic or non-diabetic he recommended a test-meal of bread and butter and marmalade, and testing the urine after it. Weakness of assimilative power would then be brought out. Great variations would occur in diabetics in relation to time; they did not live constantly in the same condition. There was no doubt that traces of sugar were present in normal urine, so that everyone might be said to have glycosuria to a trifling degree. But in diabetes it was in proportion to the carbohydrates of the food which reached the blood as sugar and passed into the urine. This resulted from defective assimilative power, as seen in alimentary diabetes. In addition to this source in composite diabetes there was the breaking down of proteid tissue. He considered non-diabetic glycosuria as independent of assimilation of food. It might arise from asphyxia from any obstruction to respiration, even paroxysms of whooping-cough. In convulsions or coma there might be sugar in the urine; so also in connection with lactation, or as a result of poisoning by carbon monoxide. An anæsthetic might throw a little sugar into the urine. Lager-beer glycosuria is recognized in Germany.

Dr. Saundby impressed on the meeting that alcohol should not be overlooked in considering any case of glycosuria, which often appears after immoderate use, and in some alcoholics is persistent. He thought a clinical grouping practical—where they knew the cause and could remove it he would not call it diabetic glycosuria. Where they could not find the cause, and the sugar persisted, it was probabl diabetes.

Dr. Rose Bradford said it must now be recognized that sugar may be present in small quantity in health, and also that it may appear in the urine as a result of morbid conditions, not diabetic. He added to those already named in the debate injuries and perhaps functional disturbances of the central nervous system, and perhaps muscular fatigue, and some toxic substances. He though five varieties of diabetes might be described, though in the present state of our knowledge, they could all be separated clinically. They are alimentary, hepatic, pancreatic, renal, and lastly, cases arising from a primary disintegration of the tissues. From these groups he omitted the nervous as experimental evidence points to glycosuria, not diabetes as produced by nerve lesions.

Dr. Robert Hutchinson resumed the debate on the second evening—the 17th inst. He laid down that the object of treatment was to rid the blood of the sugar, which was itself a danger, for it produced the thirst and caused complications. Obstinate ulceration, sloughing cellulitis, pruritus, etc., would begin to heal when the sugar was got rid of. Moreover, the power of assimilating carbohydrates got less and less as long as their ingestion was unrestricted, but tended to return, and might almost sometimes quite reach the normal after a period of dieting. Sugar-free milk could now be obtained, so could casein-breads and dieting was accordingly easier. A little alcohol, he said, helped the patient to take more fat, the most important thing for every diabetic.

Dr. Hector Mackenzie spoke of glycosuria in reference to insurance. He emphasized the fact that sugar might appear in the urine more than once or twice and et the p rson not be diabetic; about 33 per cent. of corpulent people had glycosuria. If taken in time and dieted it disappeared, and the corpulency was lessened. Some gouty subjects would occasionally pass a little sugar.

Dr. Ewart remarked on the unsatisfactory results of drug treatment, particularly opiates.

Dr. C. C. Gibbes (President) referred to the common statement that in chronic nervous congestion sugar was found in the urine, but in 200 consecutive cases he had only found it once, and then it was due to alcoholic excess. He had watched that patient for three and one-half years and sugar followed every excess.

Dr. White, in reply, referred to a number of the points which had been brought out in the discussion.

A verdict of death from arsenical poisoning, due to error on the part of the patient, was returned on Friday, in a case which seems by no means clear. Dr. Fawcett made a post mortem at Guy's and found no ulceration or irritatioin of stomach or intestines, and thought ptomain po soning the most probable cause of death. The appearances, he said, were altogether negative, so he did not believe death was due to arsenic, although the patient had been taking it medicinally. Coroner Troutbeck directed a post-mortem to be made by Dr. Freyberger, who said he found traces of arsenic and bismuth in the heart, kidneys, and blood, and the cause of death was collapse from excessive vomiting and diarrhœa, produced by the arsenic, which he also found in the medicine bottle in his room. He believed the death might have resulted from the patient taking the same doses he had left off with formerly. The stepmother said the young man had formerly taken medicine which she was told contained arsenic, but had left it off for six weeks. He then began again,and took it night and morning for three days before he died.

Dr. T. J. Maclagan died on the 20th inst., aged sixty-five years. He took his M.D. at Edinburgh in 1860. He practised in Dundee, and was so appreciated that he was appointed to an examinership in the University of Aberdeen. In 1875 he published his first contribution on salicin in rheumatic fever—a subject which he followed up with energy, as seen in his work on "Rheumatism: Its Nature, Pathology, and Successful Treatment," which appeared five years later, followed by a second edition in 1826. He came to London before the first edition (1880 or 1881) and rapidly acquired a high-class practice. He was appointed physician to the Prince and Princess Christian of Schleswig-Holstein, and was greatly esteemed by many distinguished patients and all his confrères, who had the pleasure of knowing him. His health failed about a year ago, and cancer of the stomach became obvious. A laparotomy was done, and only gastroenterostomy could be carried out, which was a relief to him, but he sank about a month afterward.

The High Court has for three days been occupied with the subject of the spread of smallpox in connection with a claim against a health authority of negligence. The case is still unfinished and cannot, therefore, be discussed. But one bit of evidence may be quoted. The medical superintendent of the smallpox hospitals of the Asylums Board said out of 700 nurses and scrubbers employed, all but one were revaccinated, and all steered clear of smallpox except that one.

The *Medical Register* is out and shows an increase in the profession of 320.

The *Dentists' Register* has also been issued. It contains 4,617 names.

OUR PARIS LETTER

(From Our Special Correspondent.)

STATISTICS OF THE NEW PASTEUR HOSPITAL—QUENN'S OPERATION FOR FRACTURE OF THE PATELLA—DE LAVARENNE, THE EDITOR OF THE "PRESSE MÉDICALE" CRITICISES THE REPORT OF ROUSSELLE, A MUNICIPAL COUNSELLOR ON THE LABORATORIES OF RADIOLOGY—THE CRUSADE AGAINST ALCOHOLISM.

PARIS, April 7, 1903.

THE statistics and financial statement of the new Pasteur hospital have just been published. The expense for food for each patient is only eighteen cents a day. The total expenditure is five francs. Five hundred and twenty-two cases of smallpox were treated with a mortality of 18 per cent. There were 285 cases of diphtheria treated, with only 13.9 per cent. of mortality, or 10 per cent. if the patients dying in the first twenty-four hours are eliminated. There were ninety-one cases of measles with no deaths, fifty-four cases of scarlet fever with only one death.

Dr. Quénu described, at a meeting of the Society of Surgery, the method he uses in suturing the patella in fracture of this bone, and his report gave rise to a discussion which shows how different the views of well-known surgeons may be on the same topic. Professor Berger, who is considered in Paris as an authority on questions of this sort, declared that in some cases most serious results ha occurred after this operation. Suppuration in two cases, amputation being necessary in one, and death taking place in the other. One of his own patients suffered from necrosis of the patella, with subsequent ankylosis. If perfect asepsis cannot be obtained, it is best to content oneself with holding the fragments together with diachylon, and instituting massage and mobilization after

twenty-five days. Dr. Lucas-Championniere has carried out suture of the patella without a single accident sixty-eight times. He does not believe in massage unless there is considerable atrophy, but he insists upon mobilization from the fourth day. With patients who are old or cache tic, the best treatment is massage and mobilization as soon as possible. Lastly, Dr. Lejaes, who is of the younger school of surgeons, said that he favored "cerclage of the patella," with massage and mobilization after the twentieth day.

The physicians of the Paris hospitals have sought to have a laboratory of radioscopy and radiography established in each hospital of some importance, and their efforts have been opposed by a member of the municipal counsel of Paris, Henri Rousselle, who presented a report by which he endeavored to have one special laboratory favored, which was under the direction of Contremoulins, who is not a medical man. De Lavarenne, the editor of the *Presse Médicale*, wrote an article on the subject, in which he criticised severely this project, and called attention to the favoritism shown toward this one laboratory. This called forth a most virulent answer from Rousselle, which the editor of the *Presse Médicale* was obliged to publish in the same part of his journal as that where his own article had appeared. In this reply, Rousselle seems to indicate that radiology is to be a method by which the errors of diagnosis of physicians may be controlled and exposed, and in the latter part of his diatribe, he seems to consider that the physicians of the hospitals are manœuvring for their interests against those of the public in insisting on radioscopy, which does not leave any indication of the result obtained. The medical society of the hospitals has been drawn into the discussion, and it seems likely that the physicians will carry the day. In connection with this the following incident took place at the Broca Hospital when President Loubet visited it a few weeks ago. Dr. Brocq, the celebrated dermatologist, drew the attention of the President to the fact that the sum put aside for the electrical laboratory had been suppressed for the current year. The President promised Dr. Brocq that the matter should be seen to.

Another subject which has caused a good deal of discussion is the question of alcoholism. The experiments carried out recently in America by Atwater showed that alcohol could serve to produce heat in the human body, and the advocates of alcohol have sought to find in them an argument tending to show that alcohol is a food. Dr. Duclaux, the director of the Pasteur Institute, has published a species of manifests, in which he seems to indicate that alcohol has been unjustly accused, and that it can certainly render certain services. Just before this a large white poster had been posted up all over Paris, in which the dangers of alcoholism were described in a most emphatic manner, and this was signed and countersigned by M. de Lelves, the prefect of the Seine, and Professor Debove, the dean of the medical faculty. This was a direct attack, which was not allowed to pass unnoticed, and it seems that an action will be brought against the printers and signers of this proclamation.

Two more posters have appeared on the walls of the city, one of them of a humoristic nature and the other giving different extracts from the writings of eminent men, in which they describe the ill-effects of alcohol. This is certainly an important question in France and the Academy of Medicine was asked to give a list of the essences which were dangerous, the plan being to tax heavily the latter. There was a long discussion at the Academy, it being finally voted that all essences were injurious, and no special distinctions being made.

OUR LETTER FROM THE PHILIPPINES.

(From Our Special Correspondent.)

INSANITARY CONDITIONS IN MANILA—DISPOSAL OF EXCRETA—INDIFFERENCE TO SMALLPOX—ABATEMENT OF CONSTANT BELL-RINGING—CIVIL-SERVICE EXAMINATION FOR MEDICAL APPOINTMENTS.

MANILA, February 25, 1903.

THE most serious obstacle to the sanitary regeneration of Manila is undoubtedly found in the absence of proper drainage and sewerage, and of any provision for the suitable disposal of household wastes; and in the absence of these prime sanitary essentials much of the work of the sanitary officials must be nullified. Until these deficiencies are removed Manila can never hope to become a healthful city—and to remedy these defects means, not only almost the reconstruction of the city, but a total change in certain customs of life on the part of the great mass of its inhabitants. The improvements urgently needed are far-reaching and costly, and will require a long time for their complete establishment.

The Spaniards made practically no effort to solve the problem of the disposal of excreta and house wastes in this city of more than 300,000 inhabitants, and as a consequence the site upon which it is built is saturated with the organic filth of centuries, and it is no wonder that epidemic diseases, once introduced, take root and flourish. The Filipino native, left to himself, makes no special provision for the disposal of excreta and house refuse. His flimsy house, elevated from four to six feet above the ground on bamboo poles, has neither piped water supply nor sewerage. Usually a hole is cut in the floor through which the excreta are passed and the wastes are thrown to the ground below, whence the solid parts are removed by the pigs, dogs, and chickens that act as scavengers to every true Filipino household. The native never troubles himself to do any cleaning up around his domicile, the vicinity of which is soon foul and malodorous. In some instances a neighboring bamboo thicket or clump of banana plants is resorted to in attending to the calls of nature, but even this is not commonly the case. Such a thing as the provision of a covered privy never occurs to the average Filipino, and soil pollution, with probable ultimate contamination of the water supply, goes on unchecked except for natural processes of purification. In most of the old houses of Spanish construction the disposal of excreta is equally insanitary. In these, on the low-lying site of Manila, a privy vault of masonry is usually constructed above ground in the basement of the house, and connected by a chute with the privy seats on the floor above. Usually this surface vault or cesspool is built in a corner, so that two of the basement walls of the house may serve also as the walls of the vault. These vaults are made large, so as to avoid the necessity of frequent emptying, and their bottoms are made of loose stones, so as to facilitate the removal of liquids by soakage into the soil. In many instances these vaults extend as high as the second story of the house and contain the dejecta of an entire family for many years. This vault, in conformity with the invariable Spanish custom, is always in close proximity to the kitchen. As the horses are usually stabled on the ground floor, such houses are always malodorous, and bad smells are especially offensive in the rainy season. These vaults are frequently in close proximity to the household well, the water of which is soon contaminated. This Spanish system has the advantage of keeping the excreta in one place instead of strewing it broadcast, but the disadvantage of greatly interfering with the natural processes of purification by sunshine and fresh air. The walls of the closet chute soon become smeared with fecal matter and saturated with urine, and the whole putrifying mass gives off mephitic gases of light specific gravity, whose only avenue of escape is through the house.

In a few of the better class Spanish dwellings, where a watercourse is convenient or a roomy leaching cesspool has been built, an attempt is made to remove the excreta by water carriage. In these instances the plumbing is usually badly installed and the fixtures are of an insanitary pattern. The first essentials for a proper sanitary installation are ignored. Sometimes there is no water flush, and usually there is no water seal to prevent the return of malodorous gases. When a water seal does exist, the distal side of the trap is not usually vented. At the time of the capture and occupation of the city by the United States troops the main water-closet in the palace discharged into a tight cesspool through an unvented trap, and the pressure of the confined gases periodically spattered the filthy water from the trap over the floor of the closet. There is no general sewerage system, and only a very small proportion of the houses of Manila have water carriage.

As the best method of securing immediate improvement over existing insanitary conditions, with the funds at their disposal, the sanitary authorities are installing the bucket system for the disposal of excreta. Already some 12,000 buckets are in use. This system is undoubtedly inferior to the earth-closet system, but the latter could not be installed because of the practical impossibility of securing a sufficiency of dry earth in the rainy season, and the greater cost and difficulty of disposal. The buckets are of wood, tarred inside, heavily hooped, provided with handles, and having a lid which can be screwed tightly in place by means of thumb-screws, for removal. These buckets are collected at frequent intervals, taken out to sea, emptied, washed, and disinfected. At present scows are used for this purpose, but a dumping barge of special pattern is now being constructed to take their place. In the native districts there are public bucket latrines, separate for men and women, which the natives are forced to use. This bucket system, while far from satisfactory, is yet a great improvement over conditions as they formerly existed

Water carriage is, of course, the only satisfactory method for the removal of excreta, but to be thoroughly

satisfactory there must be a sufficiency of water for flushing at all times, and sufficient fall to insure proper scouring of the pipes. Also the sewer pipes should not be liable to injury or disturbance, and the sewage should be discharged so as to avoid the creation of a nuisance. These desiderata cannot be obtained in Manila. The piped water supply, even without sewerage, is insufficient for the needs of the population of the city, though this deficiency can be remedied. During half the year practically no rain falls, while during the remaining six months the rain falls daily in torrents. Any combined system of sewerage large enough to carry off the storm water with the sewage during the rainy season must necessarily be so large as to be imperfectly flushed during the dry period. A separate sewer system will, therefore be necessary. Serious engineering problems are also presented with reference to securing a fall sufficient for proper flushing; for the city of Manila lies on an almost level site, only a few feet above high-water mark, and with a level of the ground water, which, in the rainy season, almost coincides with the surface of the ground. Without the installation of expensive pumping stations on the Liernur system, and endeavoring to rely upon the natural fall to secure water carriage, it will be necessary to divide the city into many districts, each with its separate sewer system. To do this, means that certain of these systems must discharge their sewage in localities and under conditions which render it inevitable that nuisances of a more or less offensive nature will be created. Finally, the frequency of earthquakes in Manila, and their destructive effects upon any underground system of piping, must receive the most serious consideration. It is evident that, for the above reasons, the sewerage of Manila becomes a most difficult sanitary and engineering problem, and one which must be attacked most intelligently, in order to secure even fairly satisfactory results.

While the Liernur system would seem to promise the best results, several pumping plants would be necessary, and the cost would be great. In the Philippines, with so many improvements urgently needed, the cost of any undertaking must be carefully considered. Manila is cut in two by the Pasig river, and is further subdivided by numerous tortuous esteros, or sluggish creeks, which ramify from the river in all directions. At present these receive much sewage and filthy wastes, and are little better than open sewers. All of them are tidal, and are fairly well emptied at low water. At present many of them are obstructed, and their sluggish current impeded by a heavy growth of rank vegetation, which strains out and retains the solid particles to putrify and pollute the air, even in some of the best residential portions of the town. The stench which arises, from this cause, from the moat which encircles the "walled city" is frequently almost sickening on a warm, quiet night. These foul esteros not only give rise to serious nuisances in their present condition, but are pestilential, and furnish ideal breeding-places for mosquitos, which are one of the plagues of Manila and have much to do with the elevation of its sick rates. Breeding by millions along the boggy shores of these esteros, these mosquitos make life a burden in some parts of the city after nightfall. At present Manila has no proper drainage system for the removal of storm water, and the construction of this, and the sanitary improvement of the esteros should be accomplished together. Rain leaders from the houses are not provided for storm water, the ground is not underdrained, and surface trenching is not provided for the conduction away of the rainfall. A part ultimately finds its way to the river, but much collects in slight depressions and only disappears as a result of evaporation and soakage. A stagnant pool of filthy water usually stands under each native house during the rainy season, and even the better class of dwellings is not exempt in this respect. In view of these facts and that no sewer system could provide for the proper removal of storm water, a general plan of surface drainage, with these esteros as the main arteries, would seem to be desirable. For this purpose, and to destroy the breeding-places of the mosquitos, these esteros should be converted into open drains, their present crooked channels straightened and their bottoms dredged to a uniform fall. To do away with their present marshy surroundings and the appearance of foul-smelling mud flats at low water, the sides of these esteros should be walled up with stone—an abundance of readily quarried stone, hardening on exposure to the air, being available a few miles above the Pasig river, or the stone in the walls of the "walled city" which now interfere with the sanitation and commercial expansion of Manila, could, with advantage, be used for this purpose. To prevent interference with the free flow of water through these esteros a thorough removal of existing vegetation and other obstructions is required. Any slight depressions in the surface of the ground should be filled up or drained by trenches into the nearest estero, so as to secure the ready removal of storm water. As the tidal variation at Manila is about three feet, this rise and fall would insure the evacuation of the contents of the esteros at low water, while during the rainy season the heavy rainfall would be of great value in keeping them scoured out. Under such improved conditions of construction, it would seem that house sewage might be safely run into these esteros without the creation of any serious nuisance, and that disposal in this way would be very much less expensive, though probably not so ideal from the sanitary standpoint, as the establishment of the Liernur system of sewerage. The proposed system, if open drain, would require relatively small amount of attention, and would not be liable to serious injury as a result of earthquakes. Of course the constant discharge of suspended matters into the Pasig would add to the bar continually forming at the mouth of that river, and this obstruction would have to be dredged out a little more frequently than has been required in the past. It is certain that only by this improvement of the esteros can Manila be properly drained and the mosquito pest be eradicated.

Smallpox has developed in the provinces to a considerable extent. In the last six weeks 210,000 units of vaccine virus have been sent out from the government laboratory. The disease is most prevalent in Isabella province, in northern Luzon, though many cases have occurred in the other provinces and in the southern islands. In Manila more than 200,000 vaccinations have been performed in the last three months, and the disease has consequently failed to get a foothold in that city. One fatal case of smallpox has recently occurred in an army officer who had never been vaccinated, had freely expressed his disbelief in the efficiency of vaccination, and had evaded compliance with orders requiring all persons in the military service to be vaccinated before arriving in the islands. As the natives have been accustomed to regard the disease as inevitable, they take no precautions to prevent its spread, and numerous foci of infection are continually present. The proportion of pock-marked faces among the natives is quite large, and shows how prevalent this disease must have been among the Filipinos before the wholesale vaccinations instituted by the Americans. A large proportion of the numerous blind mendicants in the Philippines owe the loss of their eyesight to an attack of smallpox.

As an instance of native indifference to this disease, an instance was lately reported in which, after the public burial of a case of smallpox the mourners rode home on the open coffin—coffins here are rarely interred, but the corpse is tumbled into the grave and the hired coffin used over and over again—sitting on the edges with their feet inside. Soldiers are constantly exposed to the smallpox infection, a common method of transmission being through clothing returned to the barracks by native laundresses. In view of the greater prevalence of the disease, the troops are largely being revaccinated, nearly 11,000 units of vaccine virus having been used in the military service during the past month.

The ringing of the many church bells of Manila, at all hours of the day and night, with the many "fiesta" days, which seem to be largely celebrated by bell-ringing, has caused the passage of an act by the Commission for the abatement of loud and unusual noises. Hereafter the jangling of bells at unseemly hours in Manila, which has been a source of great annoyance to the nervous and those desiring to sleep, will be stopped. The bell-ringing for the early mass, which is celebrated before daylight, has been a special cause of complaint from foreigners.

In order to advance the plan now being agitated for establishing a general hospital in Manila, Commissioner Ide has headed the subscription list for that purpose with a donation of $10,000, the income of which is to be applied to the permanent endowment of free beds. In his letter of transmittal he states that large subscriptions had been obtained for the construction and maintenance of the defunct Cosmopolitan Hospital, and that these could probably now be secured for the projected institution. It is likewise probable that donations could be secured whereby the land on which the hospital could be located may be acquired without cost. It cannot be expected that the government will do all without the aid of those who are especially to receive the benefits of the new establishment. The new hospital is to charge for the nursing and care of those able to pay, but will provide these for the indigent, irrespective of race, without cost.

The Manila Maternity Asylum, an old institution which has done much good in times past, has recently been about to close its doors for lack of financial support. Mrs. Taft, the wife of the Governor, has undertaken to revive interest in the institution, and a strong society of American, English, Spanish, and Filipino ladies has been organized in its behalf. Much interest is being shown in the work

of securing funds to enable the asylum to continue its existence and good work.

The Civil-service Board in session in Manila announces that an examination will be held for candidates desiring medical positions under the civil government of the Philippines, in which the compensation is about $2,000 per annum. This is done for the purpose of establishing a register from which appointments can be made in the future; existing vacancies having been filled by the appointment of candidates approved by the Civil-service Commission in the United States. Owing to the needs of the service, this examination will be held in the English language, a fact which will bar from the examinations any Filipino or Spanish candidates. As the professional qualifications of these men are, with a few exceptions, not of a high order, their practical exclusion from competition will not work any especial hardship to the service.

The Board of Health has lately been brought under the civil-service rules, and the former volunteer army surgeons, who are now on duty with it will leave the service on June 30. Their places will be filled by men who have recently passed the civil-service medical examinations held in Washington, but who are untried as to their efficiency in practical sanitary service. The necessity of breaking in at one time a number of green men composing the entire medical service of the Board of Health will not conduce to the highest efficiency of the latter, especially as this is a time when the very best services are urgently required. As the pay of the new civil-service physicians is to be but $2,000 per annum, this sum will attract only very young and undeveloped men, or else those of more mature age who have not made a success of civil practice. Neither class is what is desired in order to cope properly with the tremendous sanitary problems constantly being presented in these islands.

News has just come from the island of Jolo that the Mohammedan Moros of the town of Tando, on the east coast of the island, recently made an attack with guns and bolos upon a party of sailors from a United States gunboat engaged in surveying the coast. The attack was due to a belief that the Americans had poisoned the wells of the Moros, cholera being very severe in the town of Tando and its immediate vicinity, and as many as fifty deaths now occurring there daily. The ignorant and superstitious natives do not understand the nature of the disease, and believe they are being poisoned. The many deaths and apparent inability to stamp out the epidemic up to the present time has greatly excited the people, and has made the authorities apprehensive of a general uprising of the Moros on the island. For this reason the attack was made on the naval party, and several naval signal stations, the erection of which the natives believe to have had some connection with the present epidemic, have been destroyed. Up to the present time the thorough sanitary precautions taken in the walled city of Jolo, where the American garrison is stationed, and the enforcement by strong guards of a quarantine against the surrounding country, has kept the cholera out of the city. The fact that no Americans have contracted the disease while they themselves are dying off by hundreds, has had a strong influence in convincing the Moros that they are being deliberately poisoned. It is such beliefs as these that stand in the way of the progress of sanitation in the Philippines, and which only time, civilization, and education can remove. Sanitation in the United States is child's play as compared with sanitary work in the Philippines, which everywhere is hampered by ignorance, religious superstitions, and racial dislike.

MOSQUITOS, QUARANTINE, ETC.

A REPLY TO DR. O. KOHNKE.

To The Editor of the Medical Record:

Sir: Dr. Kohnke, in the Medical Record of March 14, states that one should store knowledge rather than try to make knowledge for himself. My idea of progress is to strive to make knowledge. As to the statistical table, my belief is that my figures are the correct ones.

Dr. Kohnke does not reply to the point of my paper.

I contend that the eradication of yellow fever in Havana was due much less to the destruction of the mosquitos in Havana than to efficient quarantine.

He explains how he thinks quarantine protects, thereby agreeing with me that quarantine is the true protecting agent But to explain how quarantine protects is another question and not the one at issue.

Dr. Kohnke's criticisms do not disprove my contention that it was the improvements in the quarantine methods at the time which kept yellow fever out of New Orleans.

He does not disprove that it would not do to direct all efforts to destroying mosquitos ashore and do away with quarantine stations and their work.

He does not show that the present exemption of Havana from yellow fever is not due to efficient quarantine, but to the destruction of the mosquitos in that city.

I do not say in my paper that quarantine against yellow fever need not consider the mosquito.

Dr. Kohnke has introduced this point in the discussion, but he confuses matters. I make a distinction between mosquitos on non-infected fruit vessels and mosquitos on infected vessels; also between mosquitos on board of fruit vessels and mosquitos ashore, in the houses.

I contend that the Stegomyia on board of non-infected fruit vessels from ports quarantined against yellow fever are an unimportant factor in the transmission of yellow fever, because these mosquitos are very few in number and because they are not infected.

The investigations made on fruit vessels last summer show that on these vessels the number of the Stegomyia is 2½ per cent. That is because the Stegomyia is especially a house mosquito. Investigations also show that during fifteen years only one case really of yellow fever on fruit vessels not traceable to infection ashore was stopped at the Mississippi River Quarantine Station.

If the mosquitos on board were infected there surely would have been more than one case in fifteen years on more than one thousand fruit vessels that came from the fruit ports during these years.

Reed and Carroll do not believe that infected mosquitos reach vessels. In the Medical Record of October 26, 1901, they say: "In our opinion, the chances of infection of a vessel by contaminated mosquitos coming aboard from a house and ship in close proximity are very slight.

Therefore, it is really not necessary to fumigate the holds of non-infected fruit vessels to destroy mosquitos, especially after laborers have been in contact, for hours, with the vessel.

It is closing the door of the stable after the horse has escaped.

It is equally unreasonable to believe that the fumigation of the holds, after all this exposure, is what has preserved this city from yellow-fever epidemics for so many years.

The investigations of Dr. Grubbs at the Gulf Quarantine Station show one vessel only out of eighty-two on which the Stegomyia were numerous, and that was due to their breeding in the water barrels during the voyage, the captain said. Besides, the progeny of the mosquitos does not inherit infection, even supposing the parents to be infected.

Dr. Grubbs cites one case of yellow fever at Vera Cruz on one of the vessels with Stegomyia on board; but there was no evidence to show that the infection was not due to communication with the shore; no other case developed on that vessel. The other vessels with Stegomyia had no case of yellow fever on board.

Edward Souchon, M.D.

New Orleans, La.

Metastatic Carcinoma of the Choroid, with Report of a Case and Review of the Literature.—E. L. Oatman, after reviewing the literature on this subject, states that there are thirty cases on record which are considered genuine. The average age was 44.37 years. Twenty of the primary growths were situated in the breast, three in the lungs, two in the liver, one in the stomach and liver, one in the thyroid, one in a dermoid cyst of the suprarenal body, and two not located. There were twenty-two female and eleven male cases (due to the greater frequency of carcinoma of the breast among women). Twenty right eyes and nineteen left eyes were affected. Both eyes were involved in ten cases. The deposit always occurs posteriorly near the point where a short ciliary artery enters the globe. It appears in the corresponding region of the second eye when the latter is attacked. This indicates that the second eye is not invaded by way of the lymph channels of the optic nerve and chiasm. The typical shape is a flat discoid thickening of the choroid with a central elevation of 2 or 3 mm., gradually sloping off to a thin periphery. It spreads laterally, being an infiltration of the choroidal lymph spaces with epithelial cells which naturally follow the path of least resistance. Sarcoma, on the contrary, is a growth of the fixed tissues. The time from the first eye symptoms until vision is destroyed varies between two and eight weeks. The rapidity is due to an early and extensive detachment of the retina. Tension is increased in one-third and normal or diminished in two-thirds of the cases. The average duration of life after the first eye symptoms is six and one-half months. Enucleation is not advisable unless the eye is very painful, or glaucomatous. When a metastasis has occurred in one eye its removal does not prevent a similar deposit in its fellow.—*The American Journal of the Medical Sciences*, March, 1903.

Progress of Medical Science.

The Boston Medical and Surgical Journal, April 9, 1903.

Death from a Single Vaginal Douche.—G. DeN. Hough reports two cases. The first was a miscarriage, in which a douche of 1 to 1,000 corrosive sublimate, one quart, was given by an old negro nurse thoroughly accustomed to giving douches. Symptoms of mercurial poisoning followed, and the patient died fifteen days after receiving the douche. In the second case there was a sarcoma of the uterus. Vaginal hysterectomy was performed, and three days later a douche of peroxide of hydrogen was given. The following day the packing of the vagino-peritoneal wound was removed, and a douche of a dilute formalin solution was given. It was impossible to ascertain the exact strength of this solution. It caused the patient severe pain, and soon after it was given she passed into a condition of collapse, and in spite of vigorous stimulation, died in a few hours. At autopsy nothing was found to account for her death. The author believes that the irritant action of the formalin on the peritoneal surface (there can be no doubt that the formalin solution penetrated to the peritoneal cavity) caused the pain, and pain so severe that the patient, in her weak condition, was thrown into the condition of shock, from which she died.

The Rôle of Atmospheric Pressure in the Hip-joint.—Seabury W. Allen states that in 1836 the experiments of the Brothers Weber went to show that air pressure played an important part in the mechanism of the hip-joint; that when the joint was opened the letting in of the air made it possible for the head of the femur and the acetabulum to separate; that on replacing the femur in its former position and covering the opening into the joint with the thumb, the then air-tight condition prevented the separation of the bones. The author, doubting the truth of this statement, instituted a number of experiments which he describes. He found that on the cadaver, whether air was or was not let into the joint made no difference in the relative position of the bones. If negative air pressure does not exist in the cadaver, it seems even less likely that it would be present in life, when the tonicity of the muscles and the elasticity of the ligaments are certain factors in maintaining the integrity of the joint. It would seem from the results obtained, that what holds the bones together is primarily the cotyloid and secondarily the capsular ligaments (of course in life the elasticity of the surrounding structures helping them out), and that "air pressure" need not be considered.

Dry Hot Air as a Therapeutic Agent, with Demonstration of the Body Treatment.—Clarence Edward Skinner says that this therapeutic measure affects physiological function in two ways: First, by a direct stimulation of cell metabolism in the part treated, due to the raising of its temperature *en masse*, and, second, by a reflex acceleration of cell nutrition set up by the stimulating influence of the heat upon the numerous nerve endings in the skin. In true rheumatism pain is relieved, the disease is shortened in duration, the liability to cardiac involvement is lessened, and there are no vicious after-effects produced. Sprains are cured in a few days, arthritis deformans is greatly benefited, although it may require some time for a complete cure. In pneumonia a local treatment applied over the affected lung will relieve the pleuritis at once and remove all signs of consolidation in from two to five days. The patient begins to improve after the first treatment, and although the course of the disease is not shortened, the severity of its symptoms is very greatly decreased. Local septic infection, proceeding from ordinary traumatism or surgical operation, responds most kindly to dry hot air. The symptoms of chronic and acute nephritis are frequently very amenable to thermotherapy. The author mentions a number of other diseases in which this treatment is of value, but he is careful to state that he does not consider it a panacea for all ills, to the exclusion of other remedial measures. He goes into the question of the physiological action of the measure, and describes its action very thoroughly.

Medical News, April 11, 1903.

An Operation for Paronychia, or "Run-around."—Sinclair Tousey describes his operation, which consists in separating the attachment of the cuticle to the dorsal or exposed surface of the nail to a sufficient extent to permit the escape of the pus and the introduction of a stick of nitrate of silver to disinfect the sulcus. There is not a drop of blood drawn, and a rapid cure may be expected, most cases being entirely well in three days. Incision into the flesh is always radically wrong.

Eye Affections Complicating and Resulting from Rheumatism.—Ralph Opdyke says that there may result from an attack of acute articular rheumatism, an inflammation of well-nigh any of the tissues in or about the eye, and that these same structures frequently show a peculiar susceptibility toward the rheumatic poison. Also, these textures, when involved, quickly respond to the recognized rheumatic remedies. As a result of the blood and fibroserous changes resulting from rheumatic poison, we may have any or all of the diseases that the eyelids are liable to, and these will depend, in their character on the severity and duration of the original rheumatic attack, and will be equally liable to recurrence. It is the eye itself that is especially liable to the constitutional rheumatic diathesis. The cornea and sclera are often affected. Keratitis is often rheumatic. In the consideration of these troubles, constitutional treatment should not be overlooked. As to the eye muscles, the external rectus is the one most often affected in rheumatism. In these affections both the general practitioner and the specialist are necessary in arriving at a correct diagnosis, and this diagnosis is of the greatest importance.

Lung Surgery: Historical and Experimental.—Benjamin Merrill Ricketts states that abscess is the most frequent surgical lesion of the lung, and recovery more certain in the acute form, when operated upon. Gangrene is rather frequent, and due to many causes, such as injury, syphilis, abscess from any cause, foreign bodies, and the acute inflammatory diseases of the respiratory system. The treatment is much like that for abscess. All gangrenous portions should be removed and free drainage established. As to œdema, the surgical treatment is the same, essentially, for bronchopneumonia, hydrothorax, and œdema. Benign tumors require no interference, except when troublesome on account of size. The treatment of malignant tumors of the lung, thus far, is very unsatisfactory, as the malignant tissue cannot be entirely removed. The writer believes that more definite knowledge of conditions and symptomatology is necessary that surgery of the lung may be perfected and made more aggressive and general. Abnormalities must always be considered in dealing surgically with the lungs. Hemorrhage due to pulmonary tuberculosis should not be allowed to become fatal without opening the bony chest and the application of pressure by forceps, gauze, or otherwise. Silk, silkworm-gut, and animal tendons are the most desirable materials for lung surgery.

Journal of the American Medical Association, April 11, 1903.

Post-operative Pulmonary Complications.—R. Peterson reports six cases, their nature being indicated by the following titles: (1) Bilateral Salpingo-oophorectomy for Cystic and Atrophic Appendages. Appendectomy. Lobar Pneumonia on Second Day. Death on Eighth Day. (2) Vaginal Cœliotomy; Vaginal Suspension of the Uterus by the Round Ligaments. Bilateral Trachelorrhaphy. Perineorrhaphy. Acute Lobar Pneumonia on the Third Day; Recovery. (3) Vaginal Hysterectomy for Foul-smelling Submucous Polyp, the Size of the Fist, Projecting from External Os. Septic Vaginal Discharge. Serofibrinous Pleurisy, Right Side; Recovery. (4) Bilateral Salpingo-oophorectomy for Hydrosalpinx and Pyosalpinx in a Patient with General Miliary Tuberculosis. Bilateral Septic Pleurisy with Effusion. Death on the Fifth Day from General Suppurative Peritonitis. (5) Abdominal Hystero-salpingo-oophorectomy for Chronic Disease of the Uterus and Appendages. Left-sided Dry Pleurisy on the Fourteenth Day after Operation; Recovery. (6) Hystero-salpingo-oophorectomy for Chronic Disease of Uterus and Adnexa. Bronchitis Following Operation; Recovery. In case of an ordinary cold the author does not believe it especially dangerous to administer ether, but if there are influenza germs about, or if pneumococci should gain access to the system during a mild inflammation of the upper air passages, this infection plus the added irritation of the ether may introduce an element of danger. Hence a most careful examination should be made before anæsthesia, and it is safer unless the operation is one of emergency, to postpone intervention in the presence of even a slight cold.

Iodoform Dermatitis.—W. A. Bryan calls attention to a dermatosis from iodoform distinct from the usual condition attended with constitutional symptoms. Clinically this dermatosis appears about twenty-four to forty-eight hours after application of the remedy, and resembles at first the condition following rhus toxicodendron poisoning, but there is not so much redness of the skin, for it is obscured by the formation of vesicles. The latter may gradually involve several inches of skin around the focus. They diminish in size as they spread. They may coalesce and form blebs of considerable size, which finally burst. On removal of the cuticle the true skin appears as a thick, red, œdematous, uneven surface, often filled with little pockets of serum resembling vesicles but for the absence of the cuticle. The chief symptom is

intolerable itching. The poison, whatever it is, seems to spread through the cellular tissues of the skin, whereas blisters from iodine alone, when peeled off, leave a smooth surface, and, moreover, they are limited to the area of application and do not spread as do the vesicles from iodoform. When the latter appear, the remedy should, of course, be at once discontinued; the surface should be thoroughly cleansed with peroxide, to loosen up any adherent iodoform and specks if the latter should be picked off. Then we should apply carbolized vaselin or watery solutions of carbolic acid. It is well at each dressing to immerse the part in an astringent solution in hot water for from ten to thirty minutes. If dry dressing or dusting powders are used, they must be applied freely and repeated frequently, as they become early saturated with the exuded serum.

A Case of Typhoid Perforation with General Peritoneal Infection.—The history of the case is given by J. B. Murphy, who adds the histories of five other consecutive cases of general suppurative peritonitis. All six cases recovered. The outcome in any given case of this condition depends on the following factors: (1) The type of infection; (2) the period of time elapsing between infection and operation; (3) the tension under which the products of infection are retained in the peritoneal cavity; (4) the diffusion of the material through the cavity; (5) the administration of antitoxins and other substances to antidote or dilute the immediate depressing effect of absorbed poisons; and (6) the length of time the patient is kept under the anæsthetic and the extent to which the bowels are manipulated. Concerning the type of infection, he notes that if it be a violent streptococcus type, with little pus formation, the peritoneum is rapidly denuded of the epithelial covering and becomes a "blistered surface," through which absorption rapidly takes place. Death in these cases is caused by the large quantity of the products of infection rapidly absorbed. If the poison be diluted or the pressure under which the infective products are retained be reduced the patient may pass over the critical period to a convalescence. If it be a staphylococcus or colon bacillus infection, the denudation of the peritoneum is slower, the danger of immediate overpowering of the patient by the absorbed toxins is diminished and the fatal termination is often postponed to four or six days, until such time as the fibrinous exudate which covers the peritoneum is exfoliated, taking with it the peritoneal endothelia. A rapid and fatal absorption may then ensue.

The Treatment of Traumatic Gangrene of the Extremities.—Van Buren Knott gives the following directions: Estimate as exactly as possible the line between the healthy and diseased soft parts, and having first made, under anæsthesia, a most careful and complete disinfection and cleansing of the skin, puncturing all bullæ and removing all discharge, envelop the gangrenous area in a sterile towel up to the line selected, and at this point make a circular amputation, cutting through soft tissues and bone at the same level. Ligate carefully all bleeding points, including none of the perivascular tissue in the bite of either the forceps or the ligature. Leave the wound absolutely open, not introducing a single suture, and apply moist dressings of gauze saturated with salt-solution. The dressings to be changed two to four times in twenty-four hours, as the circumstances of the particular case demand. After seven to ten days, if the wound is perfectly clean and the condition of the patient favorable, the classical circular amputation may be made by dissecting up the flap already outlined and sawing the bone at the proper level. The advantages of this plan are summarized as follows: (1) By it we may speedily, and with the minimum of shock, remove from an enfeebled and exhausted patient the source of the infection, namely, the gangrenous tissue. (2) We may frequently make the amputation at a lower point than would be possible by the old method, because soft tissues whose vascular connections are left undisturbed are less apt to slough. (3) The freest possible drainage is provided for a sufficiently long time. (4) If the disease stops at the line first chosen no unnecessary sacrifice of tissue has been made, as the flaps have been defined at the lowest limit of safety, and the bone would necessarily have to be sawn at the same point as at the second operation. (5) If the limits of the disease have not been placed sufficiently high, the same procedure may be repeated with less danger to the patient than a typical reamputation. (6) Patients too weak and prostrated by sepsis to withstand a typical amputation may endure this much shorter procedure and be built up during the interval before the second operation is necessary

American Medicine, April 11, 1903.

Congenital Absence of Both Inferior Recti Muscles.—Edward Stieren reports this rare case. The patient was a well-developed boy of six years. When asked to look down, the patient flexed his head upon his chest, his eyes not making the slightest movement below the horizontal plane. The flexion was not accomplished in one movement, but in several jerky nods, until the line of vision was sufficiently depressed to include the object sought, when the last nod centered his vision upon the object. The lower ocular conjunctiva was freely incised and retracted in a bloodless field, revealing a total absence of the inferior rectus in the right eye. Undoubtedly the same condition existed in the left.

Glycerol of Iodine.—T. W. Williams, from his experience during a practice of forty years, is convinced that there is not in the entire range of the materia medica a more valuable therapeutic agent in strumous affections than iodine, provided it can be brought into conjunction with the diseased tissues in an assimilable form. Therein lies the whole secret of its curative powers. Glycerin is less volatile than iodine, and is a perfect solvent. It holds the iodine in such minute division as to render its particles absorbable, and they are absorbed by the venous and arterial radicles of the skin along with the glycerin, and in this way reach and enter into the tissues. The writer applies from 4 to 8 c.c. of the glycerol of iodine over the chest, in a streak along the sternum two or three inches wide, from the junction of the clavicles to the lower end of the sternum (in chronic bronchitis) or over the entire side, from the spine to the sternum (in old chronic thickened pleuras); and he repeats the application night and morning until symptoms of iodism appear, usually two or three days, then he omits a day, and resumes with about the same dose once daily.

Degeneration of the Erythrocyte.—John C. Da Costa gives the following deductions: (1) The viscosity of the erythrocytes is influenced by cellular and plasma alterations, the nature of which is obscure. The viscosity is exaggerated by the direct influence of various toxic agencies, and is diminished in many anæmic states. This phase of cellular pathology is interesting from an experimental point of view, rather than as a finding of clinical application. (2) Simple decoloration illustrates the earliest retrograde change affecting the erythrocytes, and its intensity generally corresponds to the severity of the anæmic process by which it is excited. The change may exist alone, as in the milder forms of anæmia, or it may be combined with gross necrotic degeneration of the cells, in anæmias of greater severity. (3) Deformities of shape and size are common to all pathologic blood, the degree to which such changes develop being related to the intensity of the blood impoverishment. Megalocytosis is a more serious sign than microcytosis. (4) A typical staining of the erythrocytes betrays an impairment of function, and, as a rule, is found most commonly in corpuscles the hæmoglobin content of which is subnormal. It is most striking in anæmias of the primary type. (5) The prevalence of mageloblasts indicates a fetal reversion of the bone marrow, and stamps the blood changes as pernicious, except in anæmias symptomatic of bothriocephalus latus infection and of nitrobenzol poisoning. The presence of megaloblasts indicates a severe anæmia, but not necessarily one of fatal outcome. (6) Granular basophilia, whatever may be its exact origin, should be interpreted as a sign of degeneration. It is a constant blood finding in but a single condition—lead poisoning—but is associated with many diseases involving a variable degree of blood deterioration. The experimental basophilia excited by the administration of preparations of hæmoglobin warrants a doubt as to the wisdom of using such medicaments as substitutes for iron in the treatment of anæmia.

The Philadelphia Medical Journal, April 11, 1903.

Some Remarks on the Treatment of Croupus Pneumonia.—C. S. Bradfute believes that the pneumococcus seldom or never attacks an organism in standard physical condition. Pneumonia is a self-limited disease and tends to recovery without medication. It is not a systemic disease, but a localized infection, characterized by secondary systemic disturbances, the general systemic involvement being due, primarily, to exaggerated reflex influences and, secondarily, to toxæmia. At present the therapy of this disease is purely symptomatic. The writer earnestly protests against the use of digitalis. It lessens the circulatory area without a compensatory rapidity of movement. In cases with a violent onset, aconite is indicated. It must be given very carefully. At the beginning of the treatment the bowels should be opened, but not forcibly. The principal drugs that meet the indications are cocaine, strychnine, ammonium, and alcohol. Cocaine is a general nerve stimulant of peculiar efficacy. Strychnine promotes the general activity of the spinal nerve centers and sustains the physiological functions of the end-organs. Ammonium should be given in the form of the carbonate—preferably in the

aromatic spirits. The control of the temperature is imperative. The best means is the use of cold compresses after Baruch's method. Nourishment should be constantly and frequently administered. From the onset to convalescence only liquid food is permissible. Alcohol is employed as a food and not as a stimulant. Every pneumonia patient should receive an ample supply.

A Plea for the Use of Less Drugs in the Treatment of Typhoid Fever.—J. K. P. Bowen states that castor oil is the best laxative in the beginning of typhoid fever if much solid or semisolid accumulation is suspected. Its continuance throughout the case is advisable in most instances. Salines are preferable if the intestines are distended with much fluid. Quinine is injurious in most all cases of typhoid fever. Usually no food should be given during the first week or more, unless there is some relish for it. Fewer carbohydrates and fats should be used till apyrexia or convalescence. The writer does not find sweet milk the best diet for the majority of adults or children with intestinal diseases. Casein often irritates the diseased intestine. Calomel may be given in the beginning if indicated by a pale, coated tongue and constipation. Atropine may be given in case of much intestinal congestion, and pale skin, but not for long. Turpentine is used internally for meteorism and externally with hot water to abdomen for pain, also in enemata. Strychnine may be indicated. Morphine and atropine may be given for sleeplessness in some cases, also for pain, hemorrhage, or delirium. The patient should be put in the horizontal position, and in weak patients the position should be regularly changed. There should be cleanliness, abundance of pure air and light, and cheerful and quiet surroundings. After the period of anorexia from one to three pints of buttermilk may be given daily, and plenty of pure water. Warm sponge baths with massage of skin and muscles, hot water to abdomen for pain, cold pack for hyperpyrexia and delirium in some cases. Enjoin mental rest. The physician should inspire confidence and never show any anxiety. Success in the healing art depends upon a knowledge of the principles, and clinical experience.

New York Medical Journal, April 11, 1903.

On the Physiological Action of Silver Sulphoichthyolate.—This question is discussed by H. C. Wood, Jr. He says of this remedy, known as ichthargan, that it is less irritant than the nitrate. Injected into the posterior lymph sac of the frog it causes motor weakness, and finally complete paralysis. In general, the effect is precisely similar, at least qualitatively, to that of the other silver salts. As a substitute for the familiar nitrate it is locally less irritant and decidedly less poisonous.

Methods Which Render Some Therapeutic Agents More Palatable.—S. E. Farp gives the following suggestions as to disguising unpalatable remedies: To give castor oil in one dose as a purgative, probably the "castor-oil sandwich" is the best method. It is made as follows: In the bottom of a glass put a small quantity of glycerin, then the oil, lastly half an ounce of sherry wine, and take at one draught. This will also apply to the single dose of cod-liver oil. For disguising quinine he advises the use of one grain of tannic acid to each three grains of quinine in a vehicle of syrup of tolu. Iodide and bromide of potassium and salicylic acid may be given in milk. In case copaiba and turpentine are not used in gelatin capsule form, an emulsion flavored with gaultheria comes next in order. For chloral hydrate he thinks peppermint water superior to cinnamon. Equal parts of peppermint water and simple syrup make the best solution for salicylate of sodium. Unless there is an objection to the intensely sweet taste, the syrup of glycyrrhiza answers best for sodium salicylate. If the mouth is flushed quickly with a small quantity of whiskey, the medicinal oils may be taken immediately afterward, and the disagreeable taste if not so perceptible. A few grains of table salt taken upon the tongue will produce a copious flow of saliva, and then, if swallowed with medicine which has an objectionable taste, it may in a measure be disguised. Care should be taken, however, that no chemical incompatibility exists.

Deutsche medicinische Wochenschrift, March 19, 1903.

Microscopical Diagnosts of Malaria.—Reinhold Ruge reports the satisfactory use of the Ross method, but advises that the smear be fixed for a few minutes in a two-per-cent. solution of formalin, to which ½ to 1 per cent. of acetic acid is added. By so doing the blood smear becomes firmly fixed, and is not liable to be washed off in the subsequent manipulations, as frequently occurs when no fixing is resorted to, as recommended by Ross. Since the formalin somewhat reduces the ability of the plasmodium to take up the dyes, it is necessary after having submitted the smears to the eosin and methlene-blue to stain them with dilute Manson's solution. In this manner the most delicate crescents and rings are made perfectly plain.

Bacteriological Researches in Dysentery and the Variability of the Bacteria.—Kruse, after reviewing the history of the bacteriological researches in dysentery, says that the bacillus of diphtheritic epidemic dysentery was first discovered and described by him, under the name of the "bacillus dysentericus." Shiga had a few years previously discovered the bacillus of Japanese dysentery, but had described it in such a manner that its identification according to his description was impossible. Since then it has been made plain that Shiga's bacillus is very closely related and perhaps identical with that isolated by Kruse. In addition to the chief form of epidemic dysentery there exist in Germany other diphtheritic forms of the disease, which are probably caused by pseudodysenteric bacilli. It is yet to be ascertained how widely such pseudodysenteric bacilli are disseminated. The dysenteric bacilli which have been described by French and Italian authors are in no way related to Kruse's bacillus, and it has not as yet been decided whether they possess pathogenic properties or not.

Munchener medicinische Wochenschrift, March 24, 1903.

Myopia as a Symptom of Diabetes Mellitus.—Sigmund Neuburger draws attention to the fact that myopia is often associated with diabetes mellitus and frequently, outside of the urinary changes, is the sole symptom present. Two cases are reported. In one of these the diabetic condition was first suspected through the myopic symptoms, and for one and a half years thereafter no other eye symptoms appeared, although other general diabetic appearances developed. There is no doubt but that when myopia first appears in persons of middle age or thereabouts, the presence of diabetes should be suspected and careful urinary examinations at once instituted.

Parenchymatous Syphilitic Nephritis.—F. Muhlig reports another case which shows that a parenchymatous nephritis caused by syphilitic virus may develop in the secondary stage of the disease. The patient was a male, twenty-six years of age, and the nephritis first appeared fourteen days after the detection of the hard chancre and about five weeks after the suspected coitus. The other secondary symptoms first appeared eight or nine weeks after the development of the primary sore. The fact that the nephritis was of syphilitic origin is demonstrated by the non-effect of the initial treatment (hot baths and milk diet), and its rapid disappearance upon the administration of mercury.

Influenza.—Wilhelm Ebstein reports his observations in three epidemics which occurred in Göttingen, from 1889 to 1893. In the first epidemic (1889–1890) there were observed 196 cases; in the second (1890–1891), 141; and in the third (1892–1893), 40. The clinical types of the disease were (1) a nervous, (2) a catarrhal, with especial involvement of the respiratory tract, and (3) a catarrhal with especial involvement of the digestive tract. In practice these forms are not always easily differentiated and frequently occur together, the form being assigned according to the most prominent symptoms. Frequent complications are cutaneous eruptions, middle-ear affections, and diseases of the lungs, heart and nervous symptoms. The sequelæ are also varied, and are composed of various affections, relating principally to the organs involved in the complications. The frequency and type of the complications and sequelæ vary greatly in the different epidemics, according to their severity and form. Kidney complications are infrequent as compared with other infectious diseases. It is not certain whether influenza is to be regarded as a contagious or miasmatic disease. Perhaps it is conveyed along both of these lines. The bacteriology of the disease is not as yet definitely settled. Pfeiffer's bacillus is found in the sputum in many cases, but by no means in all, and the demonstration of its absence in no way negatives a positive diagnosis. It is not unlikely that eventually it will be proven to be bacteriologically a protean disease. The treatment is non-specific and entirely symptomatic. The prophylaxis consists in the thorough disinfection of the sputum and all articles coming in contact with the patient.

Infantile Scorbutus.—Comby reports cases in which the diagnosis was not clearly made for three months. Articular rheumatism, infantile paralysis, Pott's disease, etc., were thought of. Finally, the diagnosis was made, and, although a little late, the patients rapidly recovered. After stopping the sterilized milk, fresh boiled milk, potato purée, and orange-juice were given, and the symptoms of scurvy rapidly disappeared. Recovery took place in fifteen days. The milk given at first was not a modified milk, but simply sterilized milk. It is known that under certain circumstances, sterilized milk will produce scurvy.—*Le Bulletin Médical*, March 28, 1903.

Society Reports.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, Held April 8, 1903.

Dr. William Hallock Park in the Chair.

Quantitative Estimation of Albumin in the Urine.—Dr. Norman E. Ditman read this paper. He said that the quantitative estimation of albumin in the urine determined by Esbach's method was impractical because it required twenty-four hours after beginning the procedure before the test was finished, and must be kept in a cool place at an even temperature. In the various hospitals to-day the bulk of the precipitated albumin was determined, and this varied in the different institutions Another objection to be encountered was the varying rapidity with which the albumin settled; it sometimes required five hours or more before a maximum precipitate occurred, and the results of such analysis seldom agreed. The results of centrifugal apparatus differed in the various hospitals because the revolutions per minute varied so greatly, some being below and some above 1,500. Of all the methods reported he considered that of Wassilyew, the first detailed account of which appeared in a St. Petersburg journal in 1896, to be one of the best. 10 c.c. of urine was measured off in a pipette and diluted with water to 50 c.c. Four drops of a solution of a yellow dye known as "echtgebb" was added, and then the whole triturated with a twenty-five-per-cent. solution of sulphosalicylic acid until the mixture took a permanent brick red color. The amount of albumin could then be computed by multiplying the number of cubic centimeters of sulphosalicylic acid used by the factor .01006.

A Case of Bacteriuria Resembling Weil's Disease.—Dr. G. R. Satterlee read this paper. The patient was a man fifty-six years old, non-alcoholic, but a fairly heavy eater. There was no syphilitic history. Five years previous to present illness he had an attack of acute intestinal toxæmia with temporary paralysis of lower extremities, vomiting, diarrhœa, and a partial loss of consciousness. This followed the ingestion of a large dinner the night previous. Examinations of the urine prior to present illness showed that no albumin nor bacteria were present to any appreciable extent at any time. The night before the present attack he ate a large Thanksgiving dinner. The following evening he had severe continuous pain over the lower part of the sternum with flatulence and abdominal distension. Severe chills and sweating, and a condition of shock, slight delirium, and stupor, occurred the day following. Temperature was 103°, pulse 120, and respirations rapid and labored. Heart's action was tumultuous with a loud systolic murmur at the apex and base. The second sound was accentuated. Five hours later the temperature rose to 105°, the pulse to 134, and respirations to 43. Numerous subcrepitant râles were noted all over the right lung. No tenderness over the abdomen, and there was no apparent enlargement of the liver. A tentative diagnosis of lobar pneumonia was made. Prognosis seemed bad. Three hours later the temperature dropped to 103°, pulse 104, and the general condition was improved. The morning of the next day found the temperature, pulse, and respiration normal. Skin and scleræ were much jaundiced. A large brown stool was passed. Examination of the urine showed it to be dark, cloudy, specific gravity 1026, containing 5 per cent. of albumin by volume, and no sugar. There were present granular and epithelial casts and numerous bacteria. Up to the fifth day the temperature varied from 100.2° to 103°. Large numbers of bacteria were present. From the fifth day convalescence was uneventful. The albumin gradually disappeared. The urine was always very cloudy and contained bacteria constantly, which was uninfluenced by the giving of urotropin. Bacteriuria persisted and lavage of the bladder had no appreciable effect upon it. Three months later the patient had a somewhat similar attack, but without any jaundice The bacillus isolated from the urine resembled the proteus group. Weil isolated his bacillus from the urine in a case of acute febrile jaundice. Jager found his bacillus in the urine and bodies of fowls that later caused an acute febrile jaundice. Brooks isolated his bacillus from the organs at autopsy from a case of Weil's disease. Libman isolated his from the pus of a liver abscess, which was followed by acute febrile jaundice. The results of experiments on animals showed the bacillus to be toxic for guinea-pigs, and to a less extent for rabbits. The bacillus was recovered in pure culture from all the organs. Filtered cultures of the bacillus produced no effect. The microscopical examination of the viscera of the guinea-pigs showed about the same picture in each instance. The picture presented by the original case was that of an acute febrile jaundice, which was followed by an acute nephritis and bacteriuria. The infection was probably a descending one, originating possibly from the kidneys. Acute hepatitis was marked in all cases that came to autopsy. No jaundice was observed in the experimental animals, but there was distension of the bile capillaries. In the animal which survived the inoculation from the urine bacteriuria with albumin and casts was found.

Dr. Harlow Brooks said that he had a case that followed a similar course. This patient died and the liver changes were more than could be reproduced in the animal. The disease he believed to be badly named; the name indicated that it was a specific disease when, in fact, it was far from it, for all cases did not have bacteriuria associated with it. The rarity of cases of Weil's disease was shown by a review of the American literature. Many cases of acute febrile jaundice were accompanied by albuminuria and the bacteriuria was not recorded at all. The ordinary cases of acute febrile jaundice were due to contaminated meats, such as sausages. More recent works on the subject confirmed the idea that this was not a specific disease, but that it could be caused by a group of bacilli. He said that nothing new had been brought out regarding this condition. Most cases get well, but they were apt to have relapses, as in Dr. Satterlee's case. With regard to reproducing jaundice in experiments on animals he had never been able to do so, and he thought the reason for his failure was that jaundice was a rare condition in animals that were used for experimentation. The bile acids and coloring matter were found in the urine in rabbits and were reported in the experiments made in Weil's disease.

A Case of Bilharzia Hæmatobium.—Dr. Eugene Pool reported this case, which was of interest because (1) of its infrequency in this part of the world and (2) of the phenomena shown under the microscope, *i. e.* the development of the embrio and ovum. The patient was a young man, twenty years old, a sailor. When eight years old he went to the Suez canal and remained there five years, and during that time he went in swimming daily in the Suez canal and neighboring streams, and drank much of unfiltered water. The next five years he spent on a ship in the Mediterranean. He contracted an acute attack of gonorrhœa four days after exposure; this was accompanied by very little increase in frequency in urination and very little pain. He had the characteristic discharge, which disappeared at the end of fifteen days under urethral irrigations Two weeks later, when in Algiers, it was very hot, and he noticed that his urine became diffusely red. He remained three months in Algiers. The condition persisted without other symptoms. He then went to Cuba, and the diffuse red urine changed to the characteristic hæmaturia of the disease, *i. e.* after passing a normal amount of fairly normal looking amber-colored urine, and when the bladder was apparently empty, with an involuntary spasm of the bladder there would occur an expulsion of one or two drachms of thin bloody fluid. This condition persisted up to the present time. He was nine months

in Cuba and six months in the United States. He now complained also of intense pain in the loins and a feeling of weakness which prevented him from work. Physical examination showed the man well nourished and the abdominal organs appeared to be normal. The amount of urine voided in twenty-four hours was 1950 c.c.; reaction, acid; good color; sediment, moderate in amount; specific gravity, 1019; albumin, a trace; urea, 41.3 in twenty-four hours. The sediment showed a small amount of blood and pus and a small amount of mucus. A few casts were present and some epithelial cells. Numerous ova of the bilharzia hæmatobium were found. An examination of the blood showed red-blood cells, 3,340,000; hæmoglobin, 86 per cent.; leucocytes, 6,600. A differential count showed lymphocytes, 47 per cent.; large mononuclears, 6½ per cent.; polymorphonuclear neutrophiles, 36 per cent.; eosinophiles, 9½ per cent. The doctor showed photographs showing the ovum with the spine and egg-shell between the embrio. Another showed the egg-shell from which the embrio had migrated. The third photograph showed the embrio with living cilia attached.

Blood Counts in Typhoid Fever.—Dr. H. A. Higley presented this communication. The differential leucocyte counts were made during the first week of typhoid fever. As a result of observations in uncomplicated cases, it was demonstrated that the polymorphonuclear neutrophiles were relatively and absolutely decreased, while the large mononuclears were relatively and absolutely increased in number. The small mononuclears were decreased, normal, or increased. The eosinophiles were relatively subnormal. The percentage variations he had not definitely settled, for the figures varied widely. His observations differed from those of Thayer's, who reported twelve cases examined during the first week of typhoid fever, as follows: lymphocytes, 12.9 per cent.; large mononuclears, 12.9 per cent.; polymorphonuclear neutrophiles, 74 per cent.; eosinophiles, 5.1 per cent. These counts were not made by him but by different observers. The leucocyte counts varied—in some, 200; in others, 300. Dr. Higley did not mean to throw any suspicion upon the counts reported by Thayer, but he wished to make a fair statement of the conditions. Two years ago he began a series of observations during the early days of typhoid fever, and the result obtained differed from those of Thayer. The differential leucocyte count characteristic of typhoid fever he stated was contrary to what was generally supposed during the first week of the disease. In making his studies he made it a point to show that the examinations were conducted during a specified period of the disease. His cases numbered sixteen, and the diagnosis was established in seven by an examination of the fæces, in six by the presence of the Widal reaction, and in three by the presence of the roseola, enlarged spleen, and typical typhoid course. He felt positive that he was dealing with the disease during a specified time. With regard to dating the disease, from the appearance of the eruption, authorities differed, some claiming that it appeared at the latter part of the first week, and some at the beginning of the second week; others even claimed that it preceded, or even succeeded, those days. Osler stated that it appeared from the seventh to the tenth day, and he felt justified in accepting the figures of Osler. In all cases a very careful and frequent examination was made, and he felt sure that his observations were made during the early course of the disease. The ages of the patients varied from six to twenty-nine years. The following are the average differential leucocyte counts that the doctor gave: small mononuclears, 17.8 per cent.; large mononuclears, 21.1 per cent.; polymorphonuclear neutrophiles, 59.4 per cent.; eosinophiles, 1.7 per cent. The highest and lowest variations given were: small mononuclears, 27.8–12.8 per large mononuclears, 29.3–12.1 per cent; polymorphonuclear neutrophiles, 65.5–49.1 per cent.; eosinophiles, 3–.8 per cent. His figures corresponded with those of Winters, who gave the following: small mononuclears, 5.8 per cent.; large mononuclears, 31.5 per cent.; polymorphonuclear neutrophiles, 61.4 per cent.; eosinophiles, 1.3 per cent. As a result of his work he felt certain that he had demonstrated that a differential count made in the early days of typhoid fever, particularly during the first week, was quite characteristic in a fair number of cases, and was a matter of serious consideration. Of course his experiments were as yet very limited. Among the diseases that would show a hyperleucocytosis were measles, influenza, tuberculous infections, and malaria; of these only the two latter deserved any consideration, because the first two could be differentiated clinically. He had not had much experience with the differential count in tuberculosis. Cabot had one case of miliary tuberculosis in which the eosinophiles numbered 91.64 per cent. With malaria he had only an experience with seventeen cases. The differential count in malaria and typhoid fevers he said was closely related, and, in many instances, they could not be differentiated. In a certain number of cases of malaria there was an increase in the polymorphonuclear neutrophiles So far as he had gone he found that cases of febrile malaria gave less relative number of eosinophiles than typhoid fever during the first week. In typhoid fever they were above 1.5 per cent., but below that figure in malaria. The object of the communication was to show that a differential count of leucocytes during the first week of typhoid fever was of value, and that possibly there might be differential factors there which could be utilized for diagnostic purposes.

A Simple Method for Obtaining Blood from a Rabbit.—Dr. A. Wadsworth gave this demonstration of a method for securing blood from a rabbit, which was very simple and rarely failed to give the desired result. The principle was to warm the rabbit in order to bring the blood into the cutaneous circulation; then, by tilting the animal, blood would flow more freely in the ear. By incising the ear all the blood required could be obtained.

A Convenient Medium for Growing and Storing Cultures of Pneumococci.—Dr. A. Wadsworth had experimented for some years upon media for growing and storing pneumococci used serum to which had been added enough agar-agar to give it sufficient consistency to enable it to hold together. Pneumococci had been found active even after many months when kept in this medium.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON PEDIATRICS.

Stated Meeting, Held April 9, 1903.

Henry Heiman, M.D., Chairman.

Result of Operation for Intussusception.—Dr. John F. Erdmann reported three cases, presenting two of the patients. One was a male infant, four months and three weeks old at the time of the operation. The operation was done about three weeks ago, the incision being made through the right rectus muscle. On March 20 the child had been seized with abdominal pain and passed some bloody mucus. When seen by the speaker twenty-three hours later it was in good condition, and palpation failed to reveal any tumor, although considerable bloody mucus escaped on digital exploration of the rectum. The next day he operated upon the child and found an intussusception of the ileum within the ileum, and then an intussusception of the ileum within the colon—in other words, a double intussusception. In this case the appendix was not intussuscepted, as was usual. The reduction of the iliccolic portion was easy, but that of the other portion was very difficult. The patient made a perfectly smooth recovery. The second patient happened to live in the same house and on the same floor as the first child. It was six months old,

and was seen twenty-four hours after the onset of the illness. When crying, a tumor was seen on the left side of the abdomen. The tumor was distinctly movable, but on digital examination could not be felt by the rectum, although blood was discharged. In this case shock was quite marked. At the operation it was found that there was the same double form of intussusception, except that the appendix was included. The operation was done on March 31, and the stitches were removed yesterday, there being perfect union throughout the wound. In both cases the appendix was removed. The third case was that of a child of five and a half years who had been seized with spasmodic pain in the abdomen and passed sufficient fæces and flatus to show that there was then no obstruction of the bowel. Two days later there was no passage and no elevation of temperature, but the abdominal pain was continuous. There was no history pointing to intussusception and nothing objectively, except the resistance in the right side of the abdomen. This case also proved to be an intussusception of the ileocolic variety. It was reduced and the appendix was removed. The child recovered.

Dr. H. Lilienthal said that he was interested to know that although the tumor was on the left side the incision was made on the right side of the abdomen. This seemed to him a safe rule, because the vast majority of intussusceptions were at the ileocolic valve or in that vicinity. Of course, the general rule was to make the incision over the site of the tumor, and he had himself usually followed this rule, although he could not recall a case of acute intussusception in which the right-sided incision would not have answered. The principal thing in cases of intussusception was to make the diagnosis early, and this was the province of the family physician or the pediatrician. The diagnosis having been made, the case was always a surgical one, and practically no other treatment seemed to him justifiable at the present time. It was true that occasional recoveries had been reported from the use of hydrostatic pressure, but this method was by no means itself free from danger. He was of the opinion that a good many cases of intussusception recovered without operation, but these were usually instances in which the symptoms were not such as to lead to the diagnosis of this condition. When the symptoms were sufficiently pronounced to suggest the diagnosis of intussusception the treatment should always be surgical.

Dr. Erdmann said that there was absolutely no difficulty in reaching the whole circumference of the abdomen through the incision on the right side employed by him. Through this incision the reduction could be readily effected, even in the region of the sigmoid, it being always borne in mind that there should be no pulling, but only a pushing manipulation in the effort at reduction. In early operations he believed it was always possible to effect reduction through the right-sided incision.

Inversion in the Treatment of Acute Pulmonary Œdema in Young Children.—Dr. Thomas S. Southworth read a brief paper on this subject, reporting a case. The employment of inversion in acute pulmonary œdema was a new procedure, if one could judge from the silence on this point in the literature. The case reported was that of a female infant, who, without premonitory symptoms, developed acute and severe pulmonary œdema. The house physician of the Randall's Island Hospital inverted the child and, with the head downward, made stroking pressure from the bronchi toward the head. This resulted in a discharge of frothy mucus from the nose and mouth, and gave immediate and marked relief. The child was then placed in bed and stimulants and revulsives were used. There was no evidence of cardiac disease. The speaker said that sudden acute pulmonary œdema without assignable cause had occurred from time to time among the children of this hospital. In the present instance the passage of much undigested food on the following day suggested that the cause might have been acute indigestion. The attack occurred just after supper, and the child had been suffering more or less from diarrhœa.

Pin-worms in the Appendix.—Dr. Erdmann exhibited an appendix that he had removed by operation on January 1 from a child five years and a half old. When first seen there was a temperature of 105° F. and a pulse of 140°, although the history stated that the child had not been ill previously. The appendix was found to contain a large number of pin-worms, and it was removed. Shortly after this he had encountered another similar case.

Dr. Henry Heiman said that this case was interesting, because the usual habitat of the pin-worm was in the rectum or descending colon When a child suffered from itching of the anus, particularly at night, thus suggesting the presence of pin-worms and yet no worms could be seen at the anus, it was well to examine the fæces for the eggs, as in this way the diagnosis could often be established.

The Surgical Features of Perforation of the Intestine in Typhoid Fever in Children.—Dr. Charles A. Elsberg presented this paper. He said that he had been able to find in the literature a total of 289 operative cases, with 75, or 25.9 per cent. of recoveries. This number included twenty-five patients who were less than fifteen years old, and among this latter group were sixteen recoveries, or 64 per cent. The speaker then reported a recent case in which he had operated upon a child for typhoid perforation of the bowel. One interesting feature of the case was that two weeks after the operation a vaginal discharge appeared, and bacteriological examination showed a pure culture of typhoid bacilli. Again, this child, six years and a half old, was the youngest on record among the operations for typhoid intestinal perforation. Among 284 cases of typhoid fever in children, Dr. J. Lovett Morse did not see one case of intestinal perforation, while Dr. Reginald Fitz saw seven cases in 192 cases of typhoid fever in children. Holt had collected 1,028 cases in children, in twelve of which, or 1.1 per cent., perforation occurred. Combining all these figures, one obtained 1,504 cases with 1.2 per cent. of perforation. The frequency of this complication in adults was usually given as from 1 to 2.5 per cent. The speaker thought the only symptom *per se* of perforation was sudden pain with, perhaps, shock and collapse; hence, he could not understand how one could differentiate this complication from peritonitis. It was seldom possible to make the diagnosis of impending perforation with sufficient positiveness to justify operation in what had been called "the preperforative stage." Of the twenty-five cases of operation considered in this paper, fourteen were between nine and twelve years of age; the youngest was six years and a half and the oldest fifteen years. Eighteen were males, six were females, and in one case the sex was not stated. According to Osler, males and females were about equally susceptible to typhoid fever, but more males were admitted to hospitals, and this perhaps explained the larger number of cases of intestinal perforation occurring in the male sex. While this might explain the greater frequency among adult males it could hardly account for the fact that 72 per cent. of all of the cases operated upon among children were males. A decided change in the appearance of the face was noted in eleven of the cases; in three the expression remained unchanged for a considerable time after the development of other fairly characteristic symptoms. The change in the facial expression never occurred early, but appeared usually after other symptoms had developed and had drawn attention to the probable existence of a perforation. Children seldom presented the sudden symptoms of collapse so commonly observed in adults. In most of the cases the temperature curve was not in any way characteristic. In fifteen of the cases the pulse became more rapid

and of poorer quality after the perforation. Vomiting was present as an early symptom in four cases. Leucocyte counts were made repeatedly in only five cases, but in all of these there was a sudden increase in the leucocytosis about the time of the occurrence of the perforation. As soon as infection of the peritoneal cavity took place there would be a great outpouring of leucocytes into the peritoneum, and the number in the general circulation would consequently be greatly diminished; hence, marked leucocytosis was likely to be a very transitory symptom, occurring only just at the time of the perforation. Pain in the lower part of the abdomen was noted as the first symptom in twenty cases. In most instances this pain was paroxysmal, and was apt to be more on the right side. Tenderness on palpation was present in every case, but there seemed to be always an appreciable interval between the first appearance of pain and of this abdominal tenderness. In nine cases there was considerable abdominal distention, and some change in the appearance of the abdomen was noted in all but three of the twenty-five cases. Rigidity of the abdominal muscles was more or less marked in fourteen of the patients. It was evident from the foregoing that there was very little difference in the symptomatology of intestinal perforation in children and adults, though the diagnosis was often very difficult in the former because of the inability of the patient to localize or describe the sensations experienced. Fitz, Keen, and Murchison were of the opinion that fully 5 per cent. recovered without operation. A case in point was reported by Dr. Elsberg. With regard to the interval between perforation and operation, and its effect upon the result, the following statistics were given: The interval was four hours in two cases with 100 per cent. of recoveries; in three cases the operation was done within the second four hours with 66.7 per cent. of recoveries; in seven cases it was done within the third four hours with 71.4 per cent.; in three cases it was done within the fourth four hours with 100 per cent. of recoveries; in one case the operation was done within the fifth period of four hours with no recovery; in one case it was done within the sixth period of four hours with no recovery. There were seven cases operated upon later than twenty-four hours after the perforation with 57 per cent. of recoveries. In one case terminating fatally the interval was not known. The perforation occurred most often during the third week and in relapses. Of fifteen cases operated upon in the first sixteen hours, 86 per cent. recovered. From the statistics given it appeared that the prognosis from laparotomy in intestinal perforation was twice as good in children as in adults. The author believed that the only possible contraindication to the operation was a moribund condition of the patient. The most important element was rapidity of operating, children standing laparotomy well if the operation were of short duration. He believed chloroform anæsthesia was preferable to local anæsthesia in children. If the perforation were very large or the infiltration extensive a piece of omentum should be sewed over the perforation. Resection of the bowel for intestinal perforation had been done once in a child of thirteen with recovery. Escher insisted that the perforation should not be sutured, but the loop of bowel should be fastened into the abdominal wound and drainage thus established. Of four cases so treated by him three recovered. The resulting shortening of the operation was not sufficiently great to be considered, but the drainage of the bowel was sometimes of value when there was already present an advanced stage of peritonitis. The surgeon should always look for multiple perforations, although in over 80 per cent. of the cases there was only a single perforation. The author was not in favor of irrigation of the peritoneal cavity except when it was soiled by fecal matter, nor did he advocate wide drainage.

Dr. Lilienthal said that the case diagnosticated as having an intestinal perforation and which recovered had presented symptoms which made those who saw it absolutely certain that there was a perforation present The existence of rigidity and tenderness of the abdomen with a history pointing to intestinal perforation would go far toward making the diagnosis. The speaker said he had operated upon a number of cases of typhoid perforation of the bowel; in one instance he had done an exploratory operation upon a child expecting to find a perforation but none had been discovered. The child showed no special shock and recovered nicely from the typhoid fever. If there were such a large perforation as to suggest excision he would prefer drainage to excision; in other cases suture would be preferable. He thought it probable that the statistics presented in this paper gave too low a mortality, because there was good reason for believing that many unsuccessful cases had not been placed on record. It was nevertheless true that when the operation could be undertaken early this surgical complication of typhoid fever would be found to be much more tractable than it had hitherto been supposed to be.

Dr. Erdmann said regarding the case of vaginal discharge containing typhoid bacilli, that he thought it possible that an abscess had broken through into the vagina, or else there had been a migration of the typhoid bacilli through the tubes. In all the cases in children that he had seen the mortality rate had been in inverse proportion to the time occupied in the operation. It would be interesting to know whether the female patients were quite young, because it was known that the older boys would drink water from any source and were much more exposed than girls to the chances of typhoid infection. If the perforation were rather high up in the ilium there was bound to be increased exhaustion, and the time occupied in suturing the perforation could not be greater than that necessary for stitching the loop of intestine to the abdominal wound. The tendency at the present day was to place more and more reliance upon the peritoneum for the removal of septic matter after the main focus had been removed, and not to resort to drainage.

Dr. M. Manges said that he had no doubt that in the the case reported as one of intestinal perforation and recovery without operation the diagnosis was correct, for he had seen this patient a number of times and had been deeply impressed with the clearness of the evidence presented. While he believed that these cases should be subjected to operation, the statistics were such as to make one wonder whether this treatment would materially improve the patient's chances of recovery. The symptomatology of this condition had been very well presented in the paper. Sometimes the only evidence of shock or collapse in these case was perspiration, there being at the same time a sudden and sharp rise of temperature. Changes in the area of liver dulness were often of the greatest significance. He, too, was inclined to believe that if all cases were reported the presentation would be a gloomy one, and this not so much because the surgical treatment was not the correct one as because one was dealing with typhoid fever.

Dr. Heiman said that the physician should be on the alert in every case of typhoid fever for symptoms of perforation when there was diarrhœa, intestinal hemorrhage, or marked distention of the abdomen. In this way only was one likely to recognize the symptoms of impending perforation. In typhoid fever, about the third week, there might be a secondary anæmia causing a shock or depression of the nervous system, which sometimes simulated intestinal perforation. The suppuration and breaking down of a mesenteric gland might also give rise to similar symptoms. He would accept the first suggestion of Dr. Erdmann regarding the possible causation of the vaginal discharge in the case reported, but the second one was hardly a possible explanation, in view of the very rudimentary state of the uterus and adnexa in a child of six years.

Dr. Elsberg, in closing, referred to the statistics that

he had presented from the Mount Sinai Hospital, and called attention to the fact that as the cases all occurred in one year it was quite probable that very different results would be noted in another year, owing to the well-known variations in type of typhoid fever. His statistics showed that the female children in his series were not, on an average, younger than the males. He had been unable to detect the symptoms of the pre-perforative stage.

Treatment of the Paroxysms of Whooping-cough by Pulling the Lower Jaw Downward and Forward.—Dr. Jacob Sobel read this paper. He said that the drug treatment of pertussis had been a thankless task, and yet it was most important to reduce, so far as possible, the number and severity of the paroxysms. About two years ago he had noticed a statement by Dr. A. Caillé to the effect that the manipulation of the lower jaw, as in a narcotized person who was not breathing properly, would control the paroxysm of whooping-cough. This has led Dr Sobel to give the method a trial since that time in his dispensary work. In all, the method had been tested in ninety-six cases. There were only nine it which it had exerted absolutely no effect upon paroxysm at the time of the child's visit to the dispensary. In infants and young children the method seemed less efficacious than in older ones because, not understanding what was to be done, the little ones became frightened and their crying interfered with the effect of the manipulation. The pulling of the jaw downward and forward was observed in a number of instances to prevent the occurrence of the whoop by instantly putting an end to the paroxysm. A search through the literature showed that this method had been first suggested by O. Naegele, but had apparently been overlooked by almost all well-known writers on pediatrics. The method was devised in the belief that the physician's chief efforts should be to control the spasm of the glottis, thereby breaking the backbone of the disease. It was this glottic spasm that produced such torture to the whooping-cough patient, and which gave rise to the terrible dread experienced by adult patients. The originator of this method put it to a test in his own children with excellent results. When standing behind the child, both thumbs should be placed against the angle of the jaw, the index fingers on the zygomatic arch and the remaining fingers upon the chin, and the lower jaw should then be pushed downward and forward. The glottic spasm was efficiently and almost instantly overcome by this manipulation in a large majority of the cases. The method could be taught to the mother or nurse, and in this way many paroxysms could be prevented and the heart, lungs, and nervous system spared much wear and tear. The raising of the entire larynx and the hyoid bone perhaps opened the glottis, but whatever the explanation, the result was most satisfactory. The only contraindication to the use of this method was the presence of food in the mouth or œsophagus. While it had been claimed that this manœuvre would also relieve other spasmodic coughs, this had not been Dr. Sobel's experience. In cases of pertussis without whoop the respiratory spasm and asphyxia were usually prevented; in cases having the whoop the latter could be usually prevented by this manipulation. Children treated in this way emerged from the condition in far better condition, being less exhausted and less emaciated because the vomiting had been controlled.

Dr. Charles Herrman said that he had practised this procedure in a number of cases, and in most instances with good result. In a crying child it was very apt to fail, and hence, as had been said, was less applicable to very young children, unfortunately just the ones in which the physician was most anxious to relieve the spasm. Recent investigation regarding the viscosity of the mucus in cases of pertussis seemed to show that this had practically nothing to do with the severity of the paroxysms. The manipulation under discussion had been found to fail in the spasm of the glottis observed in tetany and laryngismus stridulus. In whooping-cough there was a spasm of the glottis, pure and simple, whereas in tetany there was often, in addition to the spasm of the glottis, a spasm of the respiratory muscles, including the diaphragm.

New Instruments.

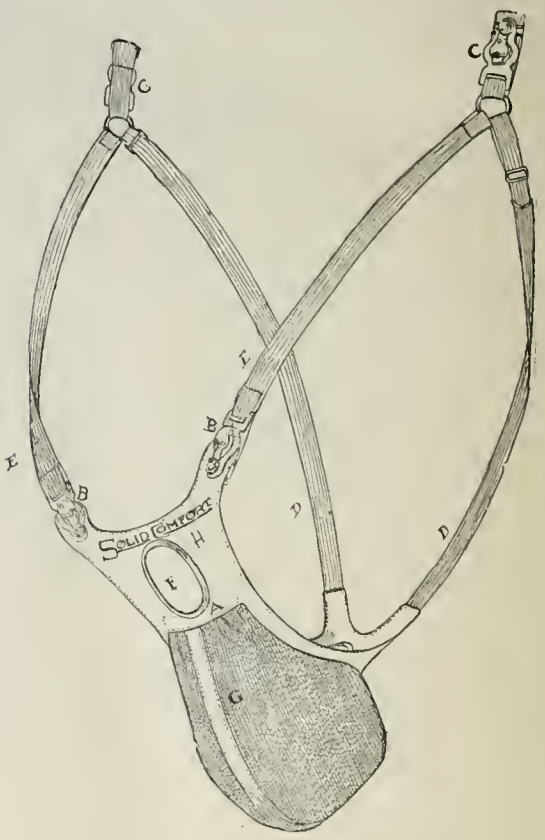
A NEW SUSPENSORY BANDAGE, CONSTRUCTED ON ANATOMICAL LINES.

By FERDINAND KING, M.D., Ph.D.,
NEW YORK.

The prime object of a suspensory bandage is to support the testicles by suspension, but the bandages found in the shops do not accomplish this purpose. On the other hand, they act, rather, as "compresses" than as "lifts."

I desire to call the attention of the profession to an improved suspensory, in the construction of which I have made it to conform, as nearly as possible, to the anatomical outlines of the parts involved. In other words, I have attempted to make an artificial scrotum.

The accompanying illustration shows the appliance so clearly that but few details are necessary to help the reader to an intelligent understanding of its most important features.



The body-piece, *H*, fits smoothly and firmly over the parts between the thighs. The scrotum, with its contents, slips through an oblong, half-oval opening into the bag which is stitched on to the front or outside. The band at *A* presses firmly into the peno-scrotal notch and prevents the testicles slipping upward and through the penis opening (*F*). And as there can be no slipping, of course there can be no chafing of the parts.

The belt-straps are attached to the upper wings of the body-piece (*B B*) by means of the Kantslip catch, the button of which passes through an eyelet, and can be easily detached. These straps meet the

understraps at *C C*, where another Kantslip catch is placed for attaching the combined ends to the undershirt, thus making it a "beltless" appliance. If, however, the wearer prefers a complete belt, he can have it by attaching an eyeletted piece of webbing and extending it from *C* to *C*.

The body-piece and bag can be detached and washed without the elastic or metal parts coming in contact with the water.

The appliance when properly fitted and adjusted is really and truly an artificial scrotum, and supports the testicles without the slightest compression displacement, or pinching.

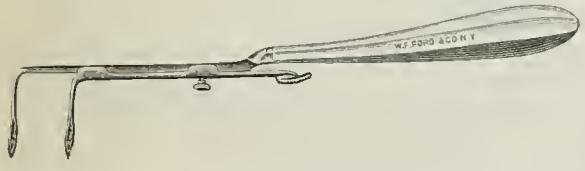
200 West Ninety-ninth Street.

A NEW INSTRUMENT FOR THE REMOVAL OF HEMORRHOIDS.*

By JOSEPH B. BISSELL, M.D.,
NEW YORK.

This rather homely instrument is more especially adapted for use in tying off hemorrhoids. It is simple, inexpensive, easy to keep sterile, small in size, light in weight, and can be made of use for various other purposes, such as a means for carrying sutures around a vascular tumor, for tying off strips of omentum, for tying varicose veins, etc. It has also been used for tying off omental tissue. It carries two needles with their sutures through at one movement. This is of advantage in that it shortens the time of an operation very considerably —a matter of great importance.

The instrument consists of two needles, fixed at right angles to a bar and parallel. The lower needle is adjustable in any position along the bar of the



other by means of a groove and a screw. The needles are of equal length, blunt, slightly curved, and with an eye at the end. They are each not unlike a Peaslee perineum needle. The screw fixes the movable needle at any point, so that the needles can be firmly held at any distance from each other that the size of the tumor requires, the handle is continuous with the first needle.

In operating, usually the thread is entered from the under side of both eyes and the needles carried through the tissues to be tied. Then, on the exit side, it is pulled out, the instrument withdrawn and the tissue tied off, and the hemorrhoid removed with the scissors. In order to prevent cutting or a secondary slipping of the ligature, as happens not infrequently in using the ordinary needle in operating for piles, this instrument is left in till the pile is amputated. This protects the ligature from injury by the scissors or knife. If it is desired to tie before cutting, it is necessary to loosen the screw and allow the adjustable needle to follow the tissues as the ligature draws them. Otherwise the needle, as it is rigidly held in position, will produce a slight tearing of the tissues.

In operations for piles with this instrument it is impossible to have a hemorrhage follow it. The vessels are under complete control before any incision is made.

The instrument is adjustable to any sized hemorrhoid, and as the principal vessels are in the center of the tumor the ligature carried in by this means completely encircles them.

If one wishes to make an incision through the mucous membrane or through the skin around the tumor, that can easily be done on either side, either before or after inserting the needles.

If there are only one or two large distinctly separate piles, another advantage is that in cutting off the piles and withdrawing the instrument before tying the ligature a very small raw surface is left to heal by granulation. Sometimes the puckering is so complete that the cut edge of skin is brought to the cut edge of the mucous membrane and union takes place rapidly almost by first intention.

The instrument is, as you see, very light, the handle is of aluminum, and to those who, for various reasons, do not use a clamp and cautery this little instrument is suggested. It is made of the best of material by W. F. Ford & Co., 315 Fifth avenue.

15 West Fifty-eighth Street.

A NEW HIGH-FREQUENCY APPARATUS.

By CHARLES O. FILES, M.D.,
PORTLAND, ME.

The modifications of the static current are of great interest and value to every one who is using that current. Dr. William J. Morton first gave us the static induced current, which has proved to be, in many respects, equal or even superior to the faradic current. He has also given us the wave current, which has proved to be of very great value.

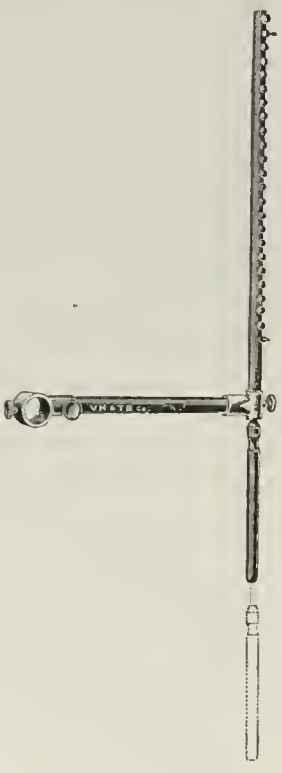
The system of high frequency alternating currents was worked out at about the same time by several different parties. The credit for this high-frequency current is due chiefly to D'Arsonval, Elihu Thompson, Tesla, and Morton. By this system currents of more than 3,000 milliamperes may be passed through the body with a frequency of alternation from 500,000 to 1,000,000 per second. This current, as is well-known, is sufficient to light an incandescent burner when passing through the bodies of two persons in the circuit without producing any sensorial impression.

It is now in order, perhaps, to explain a new high frequency apparatus, an "Interrupter" which gives beautiful violet rays from a glass electrode. This current gives us the highest frequency of any apparatus with which I am acquainted. Its therapeutic uses are varied and important. As a controller of the current in x-ray work it is very remarkable.

The "Interrupter" consists of a tube of mica about ten inches long. There are about twenty brass bulbs or knobs ½-inch in diameter that are screwed into the tube at intervals of ½-inch, the screws projecting well into the hollow part of the tube. There is a brass sliding rod with a depression in the upper side, for the contact with the terminals of the brass bulbs. The mica tubes are joined to a hard rubber rod which may be connected with any upright stand or with the case of the static machine. The brass bulbs at each end of the mica tube are provided with an eye, into each of which a wire is fastened and carried to the sliding rod of the static machine, the wire from one end to the positive pole, from the other end to the negative pole. The Leyden jars are left in the static machine. One of them is grounded by a chain running to the floor or to a gas pipe, according to the strength of current desired. The other Leyden jar is connected with a glass electrode. These electrodes are real Geissler tubes. When the tube is connected with the static machine in action, there is a spark gap of twelve

inches through which there is no current. Now, if the sliding rod is introduced into the mica tube, the spark gap is lessened and the static spark leaps from one bulb to the next, and so on, until it reaches the end of the rod. The longer the spark gap, provided the spark passes through the several knobs, the more severe the current, and the greater the number of interruptions. When the sliding rod is pushed in so that only two or three of the knobs are left for the spark to traverse, the current can scarcely be felt. This may be increased at the pleasure of the patient. This current gives a sensation of heat at whatever point the electrodes are used that is quite different from the heat given off by the galvanic current. The latter is a more burning heat, the former is rather an agreeable sensation that is not confined to the portion of the skin in contact with the electrode, but seems to affect a much larger surface. The amount of ozone that is generated by this current is very great. The room seems to be full of it.

It is unnecessary to explain the value of the inhalation of ozone. It is certainly very useful in the treatment of cases of bronchitis and tuberculosis. Is it not possible that a portion of this ozone enters the circulation through the skin? In neuralgia, rheumatism, sciatica and lumbago and myalgia it does equal if not more efficient work than the static spark or the static massage. This current has been used with vocalists with the result not only of clearing the throat, but of raising and lowering the range of the voice. Electrodes are made for use on the surface and for the cavities of the body. There is one for the ear and nose, one for the throat, and one for the vagina. It is too early yet to be able to give many exact clinical reports. One severe case of varicose veins of the tonsils was entirely relieved, the veins shrinking to their normal size, after daily treatment for about a month. There had been almost a daily hæmoptysis on arising in the morning for about two years.



The electrode for the ear is useful in very many cases of deafness caused by acoustic paralysis, and in cases of tinnitus aurium. Altogether too little attention is given to the use of electricity in aural troubles in our textbooks.

In summing up, I claim that the static current can be so accurately adjusted by the use of the "Interrupter" that it can be used advantageously in all cases. It can be used in cases that will not bear the static spark, or even the massage roller. It can be used in the ear, nose, and throat with better general results than can be obtained by the galvanic or faradic current. When it is desired to have the patient inhale ozone, no better device has yet been made than the "Interrupter."

This apparatus is manufactured by Van Houten & Ten Broeck.

Therapeutic Hints.

Backache in Women.—Backache is frequently due to pressure on the sacral nerves, often owing to constipation. The following will give relief when due to this cause:

℞	Ferri phosph	gr. ij.
	Ext. bellad.	gr. ¼
	Ext. nucis vom	gr. ¼
	Ext. cascaræsagr	gr. ij.

M.: Pro pil. i; Sig.: i pil t. i. d.

—Fenwick.

Nutrient Enemata.—Nutrient enemata should not be given too often, as there is great likelihood of rendering the bowel intolerant; once in three or four hours is suggested as proper. If the bowel is thoroughly irrigated every morning with warm saline solution, the absorption of the enema will be greatly facilitated. The following is recommended as easily borne and well absorbed:

℞	Peptonized milk	1 oz.
	Whiskey	1 oz.
	Whites of two eggs	
	Table salt	24 gr.

—Hunter Robb.

Treatment of Menstrual Disturbances.—For the alleviation of amenorrhœa, menorrhagia, and dysmenorrhœa:

℞	Kalii permang.	gr. ij.

M. Ft. pilulæ No. 1. S.: i pil. t. i. d.

—Wm. Stephenson.

For Epileptiform Convulsions.—

℞	Morphinæ sulphatis	gr. iss.
	Tinct. veratri viridis	ʒss.
	Aquæ q. s. ad	ʒss.

M. S.: Inject 20 minims hypodermatically before, after, or during the convulsion. This will greatly lessen the severity of the attack.

The following will often be of service in the treatment of epilepsy:

℞	Sodii boratis	ʒiij.
	Glycerini	ʒi.
	Aquæ q. s. ad	ʒiij.

M.: Ft. mistura (dissolve the sod. borat. in warm glycerin).

S.: A teaspoonful to a dessertspoonful t. i. d.

—Yeo.

Treatment of Graves' Disease.—Ballet, Enriques, and Mobius, acting on the theory that a thyroidectomized animal would develop in its body, a substance that would fix or neutralize the poisons of Graves' disease, have fed several patients on the milk of goats from which the thyroids had been removed. The results have so far been encouraging.

The Administration of Cocaine.—The following mixture, while it takes longer to begin acting, continues acting longer than cocaine alone:

℞	Cocaine	
	Petroleum oil	
	Almond oil āā	par. æ. q.

—*Medical Summary.*

When the skin is moist and perspirable, depressants are contraindicated In these cases, quinine, strychnine, and digitalis are to be used.—*Ibid.*

Offensive Breath.—To remove from the breath offensive odors, such as those of whiskey, tobacco, onions, and garlic:

℞	Hydrogen dioxid	10.0
	Aquæ rosæ	50.0

—E. J. Kempf.

Renal Lithiasis.—For the treatment of nephritic colic:

℞	Bromid of potassium	gr. vi.
	Cherry laurel water	♏x.
	Syrup of ether	♏xx.
	Morphine hydrochlorate	gr. $\frac{1}{20}$
	Valerian hydrochlorate	♏cxx.

Diuretics to assist the expulsion.

For the treatment of lithiasis: The waters of the various springs are to be freely drunk, but those that have the ability to cause deposits and thus enlarge the calculus are to be avoided. The indications for waters are as follows: (1) The waters are to be well tolerated by the stomach and

should cause no malaise. (2) The patient should void in the urine, within two hours, the greater part of the water ingested. (3) It should induce the secretion and excretion of well-marked uric acid precipitate. (4) It should induce free movements at least twice daily. (5) The patient should drink no other water and should avoid coarse and acid foods and fruits.

For the treatment of the diathesis: Regimen, hygiene, and medication are to be considered. In the regimen two parts of vegetable food are to accompany each part of nitrogenous diet. Red meats, veal, lamb, sweets, pastries, and alcohol are to be entirely avoided. Regular and suitable exercise is necessary. The medical treatment consists of piperizine, sidonal, and globularine, etc.

—Robin.

Surgical Suggestions.

Treatment of Lime Burns of the Eye.—The most frequent cause of burns of the eye is unslaked lime, and the burn is caused by the lime's absorbing the moisture from the tissues, which is capable of causing deep sloughing. When burn from this cause occurs, the lids should be at once everted, and the lime removed as far as possible; cleanse the whole eye with oil to prevent further slaking of the lime; diluted vinegar will answer the purpose if no oil is available; a solution of cane sugar dropped into the eye will form an insoluble compound with the lime, and may be used where convenient; when none of these methods are at hand, the eye should be thoroughly washed with water.

In gunpowder burns of the eye, the grains are to be carefully removed with a cataract needle, and an anæsthetic used.

Great prostration follows severe injuries to the eyes, and therefore the patient should be kept in bed and upon a supportive treatment.—W. Campbell Posey.

Massage in Gynecology.—There is a great deal to be learned in the application of massage to conditions of the pelvis. The following indications will prove of value in administering massage in gynecological conditions: (1) Adhesions loosely binding the uterus and adnexa in abnormal positions; (2) inflammatory exudates; (3) displacements of the uterus caused by lack of support in the ligaments and muscles by inflammatory conditions. *Counterindications.*—(1) Acute inflammation; (2) suppuration, especially tubal; (3) malignant disease; (4) pregnancy, as a rule; (5) tuberculosis. It is essential to make an exact diagnosis; to be sure that the indication is clear and that the contraindications are not present.—Palmer Findlay.

Domestic Poisoners.—The late President of the English Royal College of Physicians, Sir John Russell Reynolds, once said in my hearing, writes a correspondent to the *Manchester Guardian*, that no doctor ever went through an ordinary life of practice without seeing two or three cases which he could only explain by the hypothesis that the patient was being slowly poisoned by relations or servants. Sir John added an excellent instance, the leading features of which were these: A country practitioner was attending his vicar's wife for a mysterious complaint, which in some respects resembled incipient paralysis. The lady had a little money of her own, and was surrounded by every comfort, the vicar himself always carrying her meals to her sick room. The country practitioner, puzzled by the intractability of her symptoms, went to London and laid the case before his former teacher, Dr. Reynolds, by whose advice, on returning to his home, he secretly sent up to London some materials for analysis. After doing this he told the vicar what he had done. The vicar thanked him effusively for his friendly care and immediately drowned himself. The lady quickly recovered and erected a stained-glass window to the memory of a much-loved husband and faithful pastor from his broken-hearted wife

Books Received.

While the Medical Record *is pleased to receive all new publications which may be sent to it, and an acknowledgment will be promptly made of their receipt under this heading, it must be with the distinct understanding that its necessities are such that it cannot be considered under obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

The Heroin Habit Another Curse.—George E. Petty cites a number of cases to show that the heroin habit may become as firmly fixed as the morphine or any other drug habit. In his experience it differs from morphine in having little, if any, of the primary stimulating effect of morphine, in being more prompt and certain as an hypnotic, less powerful and less prompt as a pain reliever. It does not so greatly impair digestion or assimilation, or interfere with secretion or excretion to the same extent. It does not so quickly nor so fully arrest peristalsis, nor produce constipation to the same degree, but it does arrest peristalsis, cause constipation, lessen secretion and excretion, and interfere with the nutritive function to a hurtful degree, and its prolonged administration does result in the formation of the opium habit. When an opiate is to be used for any considerable length of time, heroin is preferable to morphine, because it can be used for a longer time without formation of the habit, and it does not so quickly alter the general health of the patient, but the same precautions should be exercised in its use as in the use of the other opium preparations. Be not deceived, says the author, it is an opiate.—*The Alabama Medical Journal*, March, 1903.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending April 11, 1903:

	Cases.	Deaths.
Measles	227	12
Diphtheria and croup	389	47
Scarlet fever	313	23
Smallpox	..	.
Varicella	83	..
Tuberculosis	284	168
Typhoid fever	39	11
Cerebrospinal meningitis	..	..

Statistical Report of the Health of the British Navy for 1901.—From the summary given in the report of the statistical sick returns of the total force serving afloat—about 98,410—the year 1901 may be regarded as very satisfactory. Notwithstanding that there was an increase of personnel of 2,880 as compared with the previous year, there was a reduction under all three headings of cases, invalidings and deaths. The aggregate number of cases of disease and injury recorded in the year 1901 furnishes a ratio of 853.83 per 1,000, which shows a decrease of 28.46 per 1,000 as compared with the ratio for 1900, and of 36.87 when contrasted with the average of the past four years. These figures compare favorably with the returns for 1889, in which year the case ratio was the lowest since 1856. The ratio of cases per 1,000 of force shows a reduction in the East Indies, China and Australia stations, and in the irregular force, the China station showing the substantial reduction of 363.1 per 1,000. The invaliding ratio of the total force, viz., 31.58 per 1,000, shows a decrease of 4.25 as compared with 1900, but an increase of 0.51 in comparison with the average for the past four years. The highest invaliding rate was on the Mediterranean station. As regards the death rate, the ratio per 1,000 was 5.34, showing a decrease of 1.93 per 1,000. Compared with 1900, and of 0.36 when contrasted with the last four years' ratio. The prevalence of and mortality from enteric fever and dysentery have greatly declined since 1900. Four cases of plague with one death and twelve cases of yellow fever with two deaths are returned in 1901, but none of cholera in that year. Among the general diseases in 1901 there were 208 cases of enteric fever, with 38 invalidings and 35 deaths, as compared with 464 cases, 98 invalidings and 124 deaths in the previous year. There were 387 cases of Mediterranean fever.—*The Lancet.*

Sabatier and the Quack.—An amusing story about Sabatier, the author of the famous "Eighteenth Century Treatise on Operative Surgery," is told by Malgaigne. Sabatier was fond of rambling about Paris, and took a special delight in listening to the quacks who, not having in those days the publicity now afforded them by the newspapers, proclaimed to such as they could get to listen the infallible virtues of their nostrums, a big drum being used as a "duc dame" which, it may be remembered, is defined by the melancholy Jaques as an invocation to call fools in a circle. One day Sabatier was listening to a quack, dressed from top to toe in red, who, standing up in a splendid carriage, charmed the ears of the bystanders with his discourse. Suddenly the orator, who had just declared that he was not an ignorant charlatan like others, but a man well thought of by the best scientific authorities, caught sight of the solemn-looking person who, with his hands on the top of his cane, seemed to be hanging on his words, and stopped for a moment. Then suddenly he exclaimed, "Look at that venerable man who is listening to me; it is easy to see that he is a man of study and knowledge. I will speak to him in the language of the learned, that is to say Latin, and you will see that he will agree with what I say." Then addressing Sabatier, he said, "Sir, this is the statement which I wish to submit to you: *Vulgus vult decipi.*" Sabatier, taken aback by the fellow's impudence, stammered out, "Quite true." "That being so," said the quack, "draw the inference yourself: *Ergo decipiatur.*"—*British Medical Journal.*

An Unusual Case of Bradycardia.—The patient of L. Lofton was a negro male weighing 187 pounds and over six feet high, enjoying good health. Speech and motion were slow but decisive. Three distinct examinations were made of his cardiac organ while standing erect, and each showed only forty-four pulsations of the heart, while as many more were made sitting, and these registered from three to five beats less. While the full recumbent posture showed that the heart's action was only thirty-two to thirty-three to the full minute. The volume, regularity, and force were good at each count. He never suffered from dyspnœa, giddiness or palpitation, and stated he had often remained under water when a boy while bathing with companions, twice as long as any of the rest. He could run, walk, and work as hard as any ordinary man of his acquaintance, and never experienced any inconvenience whatever. The heart was normal physically.—*Pacific Medical Journal.*

Health Report.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, U. S. Marine Hospital Service, during the week ending April 11, 1903:

OBSERVATIONS ON SOME LIMITATIONS OF DIAGNOSIS.*

BY EDWARD G. JANEWAY, M.D.,
NEW YORK.

MUCH as we may endeavor completely to elucidate cases of disease in order that we may be enabled to establish a correct and full diagnosis, we find only too frequently, that certain conditions may escape our scrutiny, owing either to inherent difficulty in investigation, or to false information conveyed to us by the invalid, or by those acting for him. Most of us carry in our minds certain conceptions of disease, or, better expressed, a picture, to which we expect correspondence more or less complete in each case. Rigid examination of each detail personally made, or at least a report upon each detail would save us from not a few errors. It is too frequently our own fault that mistakes arise when we accept the statement of a patient instead of the evidence of our senses. Whilst none of us would be impressed by the dogmatic teaching of student days, yet I have known medical men who could never wholly escape from the thraldom of the statements of very positive dogmatic teachers, who had no qualifying exceptions. The tendency of men's minds differs to such degree, that one teacher is filled with the thought that those facts should alone be taught which are essential to each case, lest by including exceptions erroneous conceptions should result, and hence greater harm than good should occur. Still, it has always seemed to me wise that a teacher should mention exceptions, or at least present an appendicular statement of their existence. Nor do those escape who study disease by what is called the natural method. Each case seen of a given disease tends to make up a conglomerate picture in the mind, and if none of the exceptions have been observed, they are likely to be absent from the mental concept. In this paper I will draw attention to certain of the diseases which will illustrate in different directions these ideas. At best, there can only be a short survey of the field.

Perhaps nowhere in disease does the limitation of diagnosis play a more important part than in the class of contagious diseases. It is too often assumed that the distinction of these diseases is easy, and that regular development, of course, will enable the practitioner to make a positive distinction at an early date. Yet, I have no doubt that each one present, who has been or is interested in internal medicine, has had times of serious doubt as to the nature of a given case, and the preventive measures necessary to be taken. If we draw attention to some illustrative examples, those who have no longer special interest in this branch will pardon me.

If we consult works upon varicella and variola, the rules for their differentiation will be found so detailed that a tyro could scarcely make a mistake. Yet, at one time, in looking over the distinctive features of these diseases in the same work, under varicella the characteristics of this disease were differently stated than that about varicella under the head of variola. Moreover, has it ever occurred to the members of this society, why it was that Hebra claimed that varicella was simply a variety of variola? The only explanation which has ever seemed intelligible to me is to suppose that Hebra had met cases which seemed to be, from appearances, varicella, but which proved to be variola, as a result of contact with them. Then he concluded that there was no method of distinction. Yet no one doubts the different nature of these diseases for the reasons ordinarily assigned, which it is unnecessary to repeat. But the question is raised do cases occur in which the limitation of diagnosis is reached so far as appearances alone are concerned. My own experience has been such as to convince me that at times variola appears under such guise as to resemble varicella, and in teaching I formerly made use of the term variola varicelloides to describe these cases, believing the designation original, until I found that it had been employed by others for a similar reason. The limitation is not absolute if we can have access to the following facts, viz., from what exposure did the disease originate: and what result did it produce in those exposed to it. The difficulty in employing the latter is the delay necessary to establish the diagnosis: and as regards the former, it is sometimes impossible to discover the producing case.

Let me give you a few illustrative cases: I was consulted by one who was an expert upon variola about a woman whom he thought had varicella—there seemed to me to be some deviations, though but slight, making me suspect variola. The woman was sent to the hospital as a case of varioloid. In the meantime I had advised a careful examination of the place where she had been a waitress, and also a constant surveillance of the place to which she had gone on leaving, though only for a day. The next day I visited the variola hospital, but on looking for the patient missed her. On inquiry I was told that she had been placed in another ward as a case of varicella. Those conversant with the appearance of variola were convinced, from her appearance, that this disease did not exist. In the meantime the examination of the locality where she had been at work was made, with the result that several cases of smallpox were found in the mess on which she had waited. It was also discovered that the first case had been in a man, who had come from Philadelphia with a few scabs on his face. Again, after two weeks from the time at which she had visited the house down town for the night, a child, which she had handled there, became ill with severe variola. Another case relates to the occurrences in an institution for children. Many of them were ill with varicella. The house physician became ill, and the visiting physician called in a consultant, who said that he had varioloid. I was called by this visiting physician to see the waitress in a house to which he

*Read at the meeting of the Practitioners' Society, held February 6, 1903.

had gone while visiting the house physician. This woman had been in the house for two weeks, so as to insure no outside exposure. She had all the appearances of varicella; moreover these occurrences were at a time when there was no prevalence of variola in the city. The house physician was exposed to varicella, the disease conveyed to some one away from the locality appeared as varicella. Hence it seemed almost a necessity to suppose that the house physician had varicella rather than varioloid; moreover no variola resulted in either place from these cases. I saw a child on one occasion on whose body were some twenty characteristic varicella-like vesicles, which had developed after exposure to a case of variola. Further, I have knowledge of another case in which one of the most expert examiners of variola pronounced a case undoubted varicella from which two cases of variola, one confluent, resulted. One of these was of a man confined to his room sufficiently long to assure one that outside contagion was not responsible. The consequences of mistaken diagnosis here are so considerable that it has seemed to me wise to admit doubt in some cases, and in such cases to undertake the study along the lines above indicated. Which disease is prevailing? To what in the past ten, twelve, or more days was the patient exposed? Lastly, what disease did the patient give to others? Moreover, doubtful cases should be subjected to quarantine at home till the case is made clear, and appropriate measures employed for the more severe cases.

Whilst variola varicelloides has been the occasion of the spread of variola at times, more often the severe form of variola, best known as purpura variolosa, has, in my experience, been the cause of outbreaks. The disease is assumed to be black measles, spotted fever, purpura, or, in one case which came under my observation, malignant typhomalarial fever. I was telegraphed to visit a nearby city to consult about a case of the above designated disease. A man was found who had been ill for four days with only purpuric spots on forehead and limbs, and about these there was nothing definite He had only a moderate temperature, but was evidently moribund A careful inquiry elicited the fact that he had been with a female relative, who had died on the fifth day from an illness similar to his two weeks before his sickness began. This lady had also been given a church funeral. I learned also that others in the town were ill, who had been exposed to this previous case. I told the physician that my suspicion was purpuric variola, but without convincing him. Then I asked to see one of the other invalids. This proved to be a typical case of discrete variola. Hence the diagnosis was established; the town terrified; vaccination generally performed; and the further spread prevented though a number had contracted the disease. Perhaps the most interesting case which has fallen under my observation in the difficulty of distinguishing variola relates to a woman who was reported to have died of spotted fever in 1877, at a time when we were nearing the end of an outbreak of variola. I had been in the habit of going over the death certificates with a view of discovering possible cases of variola. This woman had only been ill five days. Hence I determined to make a personal inspection and inquiry. The woman was found in a boarding-house enclosed in a coffin, waiting public burial. Inquiry showed that the phenomena of illness had been those of severe infection, rather than of cerebrospinal meningitis A careful examination of the body showed, on the abdomen, a few vesicles only, but no purpuric spots. These facts determined me to make an autopsy regarding the existence of meningitis. The result was that no evidence of that disease was discovered The conclusion reached was probable malignant variola. Vaccination was offered to those in the house, and to a man who had been the companion of the deceased, and had tended her during her illness. Result: they threatened to shoot me for making the autopsy, refused vaccination, and the man in due time became a victim of confluent variola, of which he died.

At the present day our means of distinguishing typhoid from typhus fever are much increased over those which existed when I studied, and first began the practise of medicine. In adults the distinction is easier than in childhood. Question of diagnosis has arisen to my knowledge on three occasions, where large groups of young people were concerned. I had occasion to see, after a short interval of time, a number of children ill with a fever, coming from two different institutions. No history had been kept of the illness, hence a diagnosis had to be attempted simply upon present aspect of the cases, without further knowledge than the memory of the attendants furnished. I was surprised to see how large a number could be ill with typhoid fever on the one hand, and with typhus fever on the other without characteristic eruption, history of presence or absence of diarrhœa to make a sure guide. Action of a positive nature was urgent in each instance, as the number ill was too great to be cared for at the institution (orphan asylum), whether typhus or typhoid fever. But typhoid fever was not to be mixed with typhus fever. After a few days, in one group, the attendant who had brought the cases sickened with characteristic typhus fever, and developed its eruption. In the other, the cases showed the evidence of typhoid fever, and the autopsy on one, who had phthisis, demonstrated typhoid lesions. At the present time an investigation by serum diagnosis (Widal) would in all probability have been an earlier guide. Those who had seen outbreaks of these diseases know how careful the examination of each case should be when typhus fever exists in a city. During one of the outbreaks each case of reported typhoid fever was investigated more especially if occurring in a neighborhood where typhus fever had existed. I well recall the report as regards two sisters, that one had measles and the other typhoid fever. The result of an investigation showed that both had been exposed at the same time to a case of typhus fever. One had the disease with and the other without, eruption. I have drawn attention to these groups to again illustrate the necessity and importance of a study of the etiological factor, and exposure as an important feature in establishing diagnosis. Without this knowledge no one could have made a certain diagnosis of typhus fever in the above cases.

Limitation of knowledge of exposure leads to such statements as we see at times that one member of a family has died of meningitis after a very short illness, and that later one or more of the others has had scarlet fever. The true version of such a case would usually be that the first case had been one of severe scarlet fever. Before the culture from the throats was used in establishing a diagnosis in possible diphtheria, with spots like follicular tonsillitis, I have known of quite an outbreak to follow the allowing a child with such a throat to associate with well children.

We have already heard from Dr. McBurney

somewhat of the desirability of the earlier establishment of the diagnosis of intestinal and gastric carcinoma in view of the possibility of successful radical operations, rather than the palliative procedures not infrequently resorted to. The difficulty is inherent in the nature of the diseases, which, as a rule, only become apparent when they have led to serious disorder. So far as the stomach is concerned, we can look back to the time when it was supposed that the absence of free hydrochloric acid in the gastric contents after a test-meal was a diagnostic sign of first importance. Now we regard it as valuable, but require much added information in order to feel assured that it imports carcinoma. After all, it is only when we can make out a palpable tumor that we feel inclined to advise surgical interference, and even then have doubts of the wisdom of our advice, unless the disease be so situated as to produce obstructive effects, the removal of which will add to the comfort and well-being of the patient. Few feel inclined to make exploratory laparotomy at such an early date, that this should serve as a diagnostic measure, and yet it seems to me that only in this way can we hope to reach an absolute diagnosis at such time, as should afford a reasonable hope for more than palliative surgery. Yet when we recall that case published in the Transactions of the Association of American Physicians, by Stewart of Philadelphia, in which such an exploratory laparotomy apparently disclosed a stomach so far advanced in disease that all idea of operation was abandoned; and yet, after this the patient improved to such a degree that a subsequent operation resulted in a fatal issue nearly a year later; we feel that even this measure has serious limitations. For a time the total removal of the stomach seemed a possible curative procedure, but the result in the celebrated first case shows the desirability of that earlier establishment of diagnosis. In carcinoma of the bowel we find only too frequently the limitations of diagnosis. To be sure, certain of the cases would, by more thorough study, possibly have been made out in time to do radical surgery, yet if we review the cases observed, it will be found that not infrequently the patient has only applied when serious obstructive symptoms demanded relief, and this was found to be all that could be safely given. The strangest initial symptom which I have encountered has been the development of epileptic seizure on two occasions after large public dinners.

The obstruction by a growth in the transverse colon seemed to explain this singular phenomenon. These facts were brought out in obtaining the history; but on making examination, a large mass was found in the colon, such that only a union of the ascending and transverse portions was available as a surgical measure, performed by Dr. Bull. Such an instance shows the necessity of making an examination of the whole body, even in a nervous malady coming under observation for the first time. If, however, each tumor felt in the abdomen could be assuredly accepted as evidence of growth, matters would be simpler. So, also, if evidence of stricture of the bowels could be assumed to be, of necessity, malignant, and requiring operation, advice could be given with much easier mind. Unfortunately, I have had under observation several cases which have lived for years after they had developed these symptoms, and been condemned to a fatal issue from malignant disease in a short period. Specific disease has to be given consideration, and so also have causes producing stricture other than malignant disease. It is probable that exploratory laparotomy might be performed to advantage in a certain proportion of the cases.

A lack of knowledge of a patient's antecedents is not infrequently one of the most serious limitations in establishing a diagnosis. In a paper which I read at a meeting of the Association of American Physicians, I drew attention to a number of cases in which syphilis had produced phenomena such as to be interpreted as tuberculosis, and in which this diagnosis had been considered correct by well-versed physicians. The cases were those in which the initial lesion had been contracted a number of years previously, and the disease manifested itself principally by fever, and loss of weight and strength. So little has been written about fever in the tertiary stage that not a few forget to consider it. The readiness with which, as a rule, the fever yields to anti-specific remedies shows that in cases in which a doubt is entertained, medication may easily be made to serve as a means of removing this limitation. In one of the group of cases there published, it is shown that I was led into erroneous diagnosis of tuberculosis, because the physicians in attendance on a child assured me that the parents could not have syphilis, yet an autopsy showed a syphilitic liver. The father then admitted that he had been a victim of the disease prior to marriage.

But it is not alone with this febrile tuberculous type that mistakes in diagnosis arise, but in each organ there is danger of overlooking the real disease, owing to the limitation of lack of knowledge. We must always be on our guard, and if delicacy or other reason prevents our finding out by direct inquiry, relieve a suspicion, if justified, by medication. My own experience makes the nervous system and the liver as the ones most likely to be affected, but we have to consider the possibility in obscure diseased condition of other organs, as the heart, lungs, bronchi, but very rarely of the œsophagus and stomach. Thus I have known a supposed abscess of the liver, which had been explored with negative results yield readily to specific treatment, when inquiry had brought out the admission of bygone taint. So, again, on several occasions, enlarged nodular livers, considered as carcinoma, have proven amenable to treatment. It is not to be supposed that a person may not have had syphilis and yet develop a malignant disease, and we may thus treat a patient erroneously for a time. As most of you are aware, not only has the tertiary fever given rise to a diagnosis of tuberculosis, but even typhoid fever has been supposed to exist, until, some manifestation of the syphilis becoming evident, the response to antisyphilitic measures has proved the error of the previous consideration. When, as has happened, an operation for tumor of the liver has revealed a gumma, we feel that it is better to have made the mistake of treating a case of carcinoma for syphilis, rather than the reverse, to operate on a gumma of the liver afterward cured by specific treatment.

Another instance of limitation of ability thoroughly to diagnose disease by physical signs is in the incipiency of tuberculosis in cases from which no sputum is to be obtained for examination. The result of early knowledge is so valuable to the patient, that we may well inquire how liable are we to overlook the small beginnings of disease. Perhaps in no way can we receive a better idea of the possibility of non-recognition than by the study of patients who have had a first pulmonary hemorrhage. Examined at the time of the bleeding, râles will generally tell the site of disturbance, but after a short time these may disappear, and the examiner, too frequently finding no positive signs in the lungs,

is apt to consider and tell the invalid that the hemorrhage was from the throat. Hæmoptysis is to be regarded as a beneficial circumstance, because it makes the invalid very amenable to advice. In this way I have come to look upon it as a life preserver. In this matter I am only alluding to the limitation by the absence of distinct physical signs. It has seemed to me that with students our teaching is at times too much devoted to the recognition of the defined and certain signs to which certain names are given; and that in the matter of the recognition of early tuberculosis not sufficient attention is paid to the different characteristics of the respiratory murmur.

Limitation of diagnosis is only too frequent in certain forms of heart disease, more particularly those with anginoid symptoms in whom no heart murmur is audible. Not infrequently I have known patients to obtain diverging views from different practitioners; one having been more impressed with the statement so commonly made by patients with this disease, that the distress is gastric, and that belching gas relieved the difficulty. I know of no condition which, at times, requires more careful study in order to come to a right conclusion. It would, of course, be a serious error to treat a person afflicted with dyspepsia for angina, and the reverse. A brief recital of two very instructive cases may interest you: A lady about sixty years of age had heart trouble, and complained of inability to walk more than a block without distress. She had dyspeptic symptoms, but the condition of the heart was most dreaded. Later she developed symptoms of obstruction of the bowel, for which Dr. Bull was called in consultation by the family physician. Owing to the heart condition, he hoped to escape the necessity for operation, but medical measures not being successful and stercoraceous vomiting taking place, we all agreed that an operation was imperative. Dr. Bull operated, divided a band which constricted the lower portion of the small intestine; resected this portion, and introduced a Murphy button. The patient was under the anæsthetic for an hour. She made a good recovery and, as I understand, has lost much of her old heart distress.

The other relates to a gentleman who is now entirely well and yet was supposed to be severely affected. He had lost his wife and was waiting the arrival of her remains, detained in a foreign country for a time under sanitary rules. I saw him several times in consultation, he placing the distress in the cardiac region, and had such severe spells as to require the hurried presence of a physician. The introduction of a stomach tube and the removal of gastric contents was followed by such improved condition that he has persisted in declaring that a lizard must have been removed from his stomach.

On the other hand, I have encountered instances in which the apparent dyspeptic phenomena, or the fact that the invalid was a female have led to assurances to the family that the heart was normal and the idea of angina not to be considered, in which a sudden death has disclosed the true nature of the process. Though not invariable, I believe that a careful inquiry as to the state of the patient's face during an attack deserves great consideration as a means of removing the limitation. If in an attack or attacks of this kind a patient is said to have been deathly pale, or ashy gray, then I believe that it is wise to regard the condition as one of angina, particularly if there has been neither severe nausea nor vomiting. In a number of cases in which a difference of opinion has existed as regards the nature of the disease, whether anginal, gastric, or hysterical, attention to this point has enabled me to reach a correct opinion. The physician, moreover, is not infrequently called upon to express an opinion to the surgeon whether a given heart will stand the shock of the administration of an anæsthetic and of a subsequent surgical operation? Here the physician not only feels the responsibility but also regrets the limitation of lack of absolute knowledge of the state of the heart. Yet a careful study of the physical condition of the heart, and of its behavior under exertion will enable one to decide judiciously. Slight anginoid attacks are not a barrier to necessary surgery, nor is any other form of heart disease of necessity. With the advance of our knowledge many new methods have come into vogue, and are more or less helpful in removing limitations. Of these you are aware, as well as that extravagant claims are made at the outset or, better expressed, have been made. I have already alluded to the lack of free hydrochloric acid in the gastric contents as a diagnostic sign of cancer. So, again, when optic neuritis was first brought prominently before the profession, its presence was supposed to indicate tumor of the brain, and some dreaded to make a diagnosis of tumor of the brain in the absence. Time has allowed a large number of exceptions to be accumulated. Notably, however, is the occurrence of this condition in persons about the age of puberty, in whom no explaining cause is to be found. In the same way the use of the *x*-ray has been helpful, but care is necessary in its use, and in the interpretation of its findings. No more impressive warning can be given than that which happened in another city where false teeth were supposed to be swallowed, and their location to be indicated by the use of the *x*-ray. After an operation failed to disclose them in the œsophagus, they were found by the use of more ordinary light under the mattress. So, again, the absence of the shadow of a foreign body as a renal calculus has been supposed to negative the possible presence of such body, notwithstanding the showings of clinical history and investigation, though later a surgical operation has removed a stone from the kidney. The Widal agglutination test, valuable as it has proven in distinguishing typhoid fever, only too frequently fails us in making an early diagnosis of this fever. The culture of the blood for organisms as now carried on is proving helpful—and is one of the many debts which the clinical physician owes to the bacteriologist. Yet this also may mislead.

36 West Fortieth Street.

The Use and Abuse of High-frequency Electricity in Medicine.—H. Lewis Jones concludes from a study of Denoyé's book on the subject, that high-frequency treatment possesses an influence upon the course of a certain number of morbid states, that its influence for good is not of any particular degree of excellence, but that it cannot be condemned as altogether useless. In the field of general diseases dependent upon impaired or perverted nutrition it has proved decidedly disappointing, although it was in this class of case that great things were formerly expected and predicted from the physiological effects. In diseases of the skin high-frequency applications appear at their best. Psoriasis, eczema, alopecia areata, lupus vulgaris, acne vulgaris, and impetigo all seem to be decidedly benefited by direct applications of the high-brush discharge or of sparks. Evidence of a trustworthy kind is accumulating to show that morbid growths such as sarcoma, carcinoma, etc., are favorably affected by this treatment, and also with the static-brush treatment. The method appears to be inferior to treatment by the Röntgen rays, but to be of the same essential character.—*The Practitioner*, March, 1903.

THE TOXICITY OF APPENDICITIS, WITH A REPORT OF TWO CASES OF "APPENDICULAR VOMITO NEGRO."*

By GEORGE RYERSON FOWLER, M.D.,
BROOKLYN, N.Y.

THERE is one aspect of appendicitis to which general attention has not been called, although isolated references to the matter have appeared in recent literature. I refer to its toxicity, or toxic effects upon the organism. In this connection care should be taken to discriminate between general intoxication and distant infection. By the former is to be understood the effects of toxins, or toxic bacterial products. It has even been claimed that these latter may have their origin in the closed vermiform appendix and give rise to general intoxication.[1] One of the most common symptoms of this form of toxæmia is the occurrence of icterus, with urobilinuria and albuminuria, together with the more or less rapid development of cerebral symptoms. Instances of this variety of intoxication come under the surgeon's care occasionally in connection with other sources of sepsis, as in the case of extensive burns during the time when the granulating process is under way.

Distant infection in appendical lesions may be divided into: (1) Displacement and migration of venous thrombi containing the agents of infection. (2) The absorption of pyogenic organisms into the circulation (pyæmia). (3) Infection through the medium of lymph channels at a distance from the original focus.

In the case of the first mentioned, namely, distant infection through the medium of septic emboli, metastases usually occur either to the liver or to the lungs, preferably to the latter, since this organ is in the direct route of the return circulation from the cæcal region through the superior mesenteric to the portal vein. The venous channels in the walls of the appendix itself are rarely the source of the emboli, however. These originate, in the vast majority of cases, in the veins of the mesoappendix.

In the case of the second variety of distant infection, namely, that comprehended under the old name "pyæmia," the origin of the infection, as well as its transportation, is identical with that which occurs in septic infection through embolism, namely, an infective thrombophlebitis of the veins of the mesoappendix. The formation of a parietal thrombus may or may not be followed by its early dislodgement. In the case of the former the embolic plug will lodge in the first vessel whose caliber is insufficient to afford it passage. This may occur, as before stated, first in the liver, and second in the lungs. In case the thrombus remains sufficiently long to undergo puriform softening, a mass of microorganisms may be swept into the circulation, pass the pulmonary capillaries and enter the arterial system, whence they become lodged in various parts, and give rise to the characteristic feature of the disease, namely, the development of multiple or metastatic abscesses.

Distant infection, in the sense here understood, occurring through the medium of lymph channels is not common, for the reason that the lymph vessels leading from the lymph sac which really constitutes the peritoneum, become rapidly sealed by exudate resulting from septic lymphangitis, and further progress of the infection is barred. The most common manifestation of its occurrence is in those instances in which pleuritic complications of appendicitis follow perihepatic and subphrenic abscesses. Here the barriers offered by the closely attached cæcum near the pelvic brim, in those instances in which the appendix points directly upward prevents the passage of the seropurulent collection in the direction of the pelvis, and this forces its way between the posterior and outer surface of the colon and the abdominal wall until the lower surface of the liver is reached. Here it may be arrested and form an abscess, with the liver, colon, and vertebral column as its boundaries. Occasionally the seropurulent collection may find an outlet through the foramen of Winslow into the omental bursa. On the other hand, however, the purulent collection follows the lateral abdominal wall in the cases now under consideration and forms a subphrenic suprahepatic abscess, being limited in this situation by the suspensory ligament of the liver. It is at this point that the complication loses its character as a simple extension of the suppurative process, or rather an expansion of a seropurulent collection by virtue of the necessity for more room to accommodate its increasing accumulation, and the process of infection through lymph channels occurs. The large and open stomata of the lymph channels of the peritoneal surface of the peritoneum afford passage for the infection into the diaphragm and thence into the pleural cavity, with resulting left-sided pleuritis. That this does not occur more frequently is due to the fact that the infection travels in advance of the actual progress made by the accumulation of purulent fluid, in nature's efforts to establish barriers for this excessively dangerous environment, and even the large lymph channels of the diaphragmatic area may become obliterated by this advance-guard, so to speak, of infective lymphangitis. This failing, however, infection through these channels results.

The particular complication of appendicitis resulting from its toxicity to which I wish to call attention at this time, as well as to invite discussion as to which of the methods of diffusion of infectious agents or their products is concerned in its production, is that which is characterized by vomiting of blood, to which Kirmisson seems to have been the first to call attention.[2] The blood is usually partially digested; fresh blood, or coagula is rarely vomited. In connection with this symptom there is present a condition of intense general intoxication. This symptom has received the name of "appendicular vomito negro," and the condition itself "appendicular hemorrhagic ulcerative gastritis." The symptom may arise after operative interference, or it may occur when no operation has been performed, as in the case reported by Nitzsche,[3] in which the post-mortem showed a diffuse peritonitis due to gangrenous appendicitis. It may likewise occur in cases in which but slight, if any, peritonitis is present. It has also been observed in strangulated hernia.

In a communication upon the subject by Dieulafoy,[4] which appeared about two years ago, seven cases of appendicular black vomit were reported. In a second communication,[5] which followed shortly upon the first, the fatal case occurring in connection with strangulated hernia just mentioned was reported, and the gastric alterations, as revealed upon post-mortem, described. The latter consisted of a single small hemorrhagic necrosis, about the size of a lentil, evidently the result of infection, at the bottom of which a small artery which had undergone erosion in the necrotic process, had given way. In all of these cases the black vomit occurred only after sufficient time had elapsed to permit general infection to occur. In three of the fatal cases the violence of the hæmatemesis was such that death took place from the entrance of blood into the lungs. In the other two fatal cases death was produced or accelerated by anæmia following the evacuation of large quantities of blood. Two patients recovered.

*Read before the New York Surgical Society, March 11, 1903.

In all the appendicular cases perforative appendicitis was present. In only two of the cases was diffuse peritonitis present.

In Nitzsche's case, already quoted, the patient suffered from gangrenous appendicitis, followed by diffuse peritonitis. Death was preceded by several attacks of hæmatemesis. The post-mortem showed the stomach and upper intestinal tract filled with black fluid contents. He also found in the stomach, at the fundus and greater curvature, a large number of flat ulcers, varying in size from a pin-head to that of a millet seed; some of these were covered with small coagulations of blood. Microscopic examination revealed chronic interstitial gastritis, and numerous necrotic areas of varying depths in the mucosa. Nitzsche ascribes the ulceration to the digestive action of the gastric juice upon the necrosed portions. The necrosis itself he ascribes to a toxic cause connected with the peritonitis. He advances the suggestion that bacterial products may have entered the circulation and exercised a toxic effect upon the cells of the gastric mucous membrane. The occurrence of embolic infectious influences seems to have been excluded by Nitzsche.

Two cases of appendicular black vomit have come under my observation. This first case entered the German Hospital on August 7, 1900, and was operated upon by my assistant, Dr. R. S. Fowler. The operation disclosed a perforated appendix lying free in the unprotected peritoneal cavity; a generalized peritonitis was present. The appendix was incised and the cavity of the peritoneum was flushed with hydrogen dioxide and a saturated solution of carbonate of soda in equal proportions. Glass-tube and lamp-wick drainage. There was scarcely any anæsthetic vomiting. Black vomit developed on the second day. Laboratory examination showed this to be blood. There was no increase of the symptoms of peritonitis: the function of the intestinal canal was reëstablished almost immediately after the operation. The stomach was washed out a number of times with saline solution, but without avail. Death took place on the sixth day. No post-mortem examination could be obtained.

The second case was admitted to the Brooklyn Hospital on January 30, 1903. Several attacks of vomiting had occurred before admission. Considerable distention was present; repeated enemata failed to procure bowel movements. The operation revealed an unusually large appendix almost completely gangrenous, and an absence of limiting adhesions. There was commencing peritonitis in the neighborhood. Appendix removed; local cleansing with hydrogen dioxide and carbonate-of-soda solution. Rubber drainage tube and lamp-wick drain through the flank. No anæsthetic vomiting. Black vomit commenced eleven hours following the operation. Guaiacum test showed this to be blood. Lavage appeared to beneficial at first, but the vomiting recurred and became more frequent, continuing until death, which took place forty-two hours after the operation and sixty-six hours following the commencement of the attack. Upon autopsy the stomach was found about normal in size, with many small ulcers (from two to three hundred) about the size of a millet seed, mainly in the lesser curvature. Sections taken from portions of the stomach at the site of these ulcers showed distinct ulceration of the surface of the mucosa above an area of total necrosis, the latter containing staphylococci. A second section showed an indubitable embolus, involving a vessel in the mucosa just above its bifurcation. The vessel is distended by the embolus and the latter is necrotic. The parenchyma of the tubules show signs of cloudy swelling; some of the cells are becoming coarsely granular, while others are vacuolated. Other sections again show loss of substance on the surface of the mucosa, with small round-cell infiltration at the bases of the ulcers. The apparent age of the processes in the involved tissues is such as to agree entirely with the assumption that their advent occurred following the occurrence of the appendicitis. There can be no question that these processes are septic in origin, resulting in the presence of multiple foci.

In the most conservative summing up of the matter under discussion, it may be said that the occurrence of hæmatemesis has added another to the already long list of the grave complications of appendicitis. From the pathological standpoint, it is interesting to note that the exclusion of embolism in the production of the ulceration of the gastric mucosa, by Nitzsche, is not borne out by Prof. Van Cott's findings in my own case, in which both emboli and staphylococci were found. The view that the microorganisms were transported to and produced thrombi and subsequent embolism in the vessels is sustained, first, by the fact that in one of the sections there is a focus of necrotic tissue in which the microorganisms appear, the vessels of the submucosa near this area containing recent thrombi; and second, in another section an exquisite embolus appears involving a vessel in the mucosa near its bifurcation, the vessel and its two branches containing recent blood clot.

From the clinical standpoint, however, it matters little whether the conditions present result from contact of toxins with the peptic cells, with consequent lowering of the locus minores resistentiæ followed by ulceration due to the digestive action of the gastric juice, as claimed by Nitzsche, or upon embolism of the vessels of the gastric mucosa, as shown in the cases herewith reported. The toxicity of the appendical lesion is responsible for the fatal issue which, in the vast majority of cases, ensues in either case.

That the symptom of black vomit occurs when diffuse septic peritonitis is present is probably true, but that it does not necessarily, depend upon the latter is shown by its absence in five of the seven cases of black vomit reported by Dieulafoy, by my own case, in which the inflammation was limited to the ileocæcal region, and by a case reported by Zypkin,[6] in which no peritonitis was present, the patient succumbing to retroperitoneal phlegmon and septic pleuritis on the forty-ninth day following a perforative appendicitis. The symptom of hæmatemesis was present in this case for ten days before death. It would probably be nearer the truth to say that, while the peritonitis depends upon direct infection from the appendix and takes its share in the final lethal exit by means of toxic bacterial products furnished through the lymph channels opening from this enormous lymph sac, the gastric lesions constitute one of the local expressions of a distant infection as distinguished from an intoxication occurring through the circulation. The rapidity with which this may occur has been shown, and the extreme toxicity of appendicitis, whether by distant infection or intoxication, as well as its importance as a surgical disease, has, I trust, been emphasized.

CARDIOPTOSIS AND ITS ASSOCIATION WITH FLOATING LIVER.*

By MAX EINHORN, M.D.,
NEW YORK.
PROFESSOR AT THE NEW YORK POST-GRADUATE MEDICAL SCHOOL.

Cardioptosis (cor mobile, movable heart) designates a condition in which the heart assumes a lower position and is, at the same time, more movable than normally.

The subject of cardioptosis is rather new and not yet well known. It may, therefore, be of interest first to enter upon the literature of this condition and then upon my own experience with this subject.

After Glénard[1] in 1885 had announced to the medical world his well-known doctrine regarding enteroptosis (prolapse of the organs of the abdominal cavity), it was natural to look for similar conditions in the thorax.

Cherchevsky[2] was the first to call attention to movable heart. This clinician examined in forty cases the effect of change of position on the apex beat, and found it considerable (4-7½ centimeters) in nineteen, slight in six, and absent in fifteen. Normally the mobility is 1½ to 3 centimeters; in arteriosclerosis it is greatly diminished or absent; a range of mobility exceeding 3 centimeters is abnormal. Marked mobility of the heart causes, according to Cherchevsky, nervous heart symptoms.

Rumpf[3] soon followed Cherchevsky's footsteps.

According to Rumpf, the absolute as well as the relative heart dulness are normally movable about 2 cm. to the left in the left lateral position and 1½ cm. to the right in the right lateral position; in many cases the apex beat remains at the same place. It may, however, normally show a displacement of 2 cm. on change of position.

Rumpf then describes five cases of cor mobile, in which the mobility of the apex beat toward either side was 4 cm.

Pick[4] soon afterward investigated the question of mobility of the heart in a much larger contingent, and has added clinical observations. Of 1,000 healthy persons examined, the majority showed no perceptible difference in the position of the apex beat or in the percussion sound in different postures of the body.

In 60 per cent. of these cases slight lateral mobility to the left was found on assuming the left lateral position. The apex beat moved about 1½ to 2 cm. to the left.

Pick then describes seven cases of movable heart. These were characterized by the following symptoms: difficulty in lying upon the left side; apex beat displaced 4-6 cm. to the left.

With reference to the clinical symptoms of cor mobile, Pick expresses himself as follows: "Regarding the clinical picture of abnormal mobility of the heart, we find that this condition often causes no difficulty at all. In the majority of cases, however, abnormal mobility of the heart is connected with occasional palpitation, feeling of weakness and vertigo when running and after violent exercise, as well as with the inability to assume the left and, more rarely, the right lateral position, owing to a resulting feeling of oppression."

Hoffmann[5] examined the various grades of mobility of the heart by means of *x*-rays, and came to the conclusion that changes of position of the heart, especially in various postures, are most easily determined by this means, and that these changes of position, if considerable, are of importance to the state of health of the patient.

*Read before the New York Academy of Medicine, January 15, 1903.

Schmidt[6] also is of the opinion that movable heart is the cause of nervous disorders of the heart. I will cite from his article the following words: "I wish to call attention to the fact that, according to Hoffmann's investigations, which, so far as my experience goes, I am able to confirm, a remarkable mobility of the heart, probably due to some predisposition, is often found in cardiac neurasthenia. If to this predisposition a sedentary mode of life is added, nervous heart troubles may arise even more readily than if each cause exerts its influence singly. On the other hand, it is also plausible to assume that a stooping position may favor or even hasten the occurrence of greater mobility of the heart."

Leusser[7] describes a few cases of movable heart, and makes the following points regarding diagnosis and symptomatology: "A displacement of the apex beat of 3 cm. or more to the left in the left lateral position and normal heart boundaries in the dorsal and erect positions point to movable heart."

Inability to lie on the left side was found by Leusser in all his cases. Shortness of breath and oppression result from assuming this position. Other symptoms are palpitation, feeling of fear, oppression, shortness of breath, vertigo, faint feeling, pains and stitches in the heart region, irregularity, acceleration or retardation of the pulse, rapid fatigue on exertion. The liver in all of Leusser's cases was normal.

Whereas all the authors mentioned discuss principally the mobility of the heart and speak only occasionally of a descent of the whole heart, Rummo[8] has thoroughly described the latter condition and introduced the name cardioptosis. According to him cardioptosis signifies a sagging of the heart from its normal position over the diaphragm due to a relaxation of its supports. "There is no relation to the much more common condition of enteroptosis. Persons with slim bony structures, long thorax, weak muscles, scanty panniculus adiposus are predisposed to this condition. There may exist a partial or complete ptosis where the heart rests entirely on the diaphragm. Owing to the lower position of the heart the aorta expands, and especially the aortic arch; we must listen to the valves of the large vessels in the third or fourth intercostal space, the semilunar space of Traube diminishes in size, occasionally the left lobe of the liver descends somewhat as well as the pulmonary margins, as in emphysema.

Symptoms: Feeling of oppression, precordial fear, shortness of breath, palpitation, angina pectoris, tachycardia, bradycardia, and numerous neurasthenic symptoms. The affection is congenital."

Braun[9] maintains that we must differentiate between cardioptosis and movable heart. He does not consider the latter a disease. Braun thinks that we are not justified in attributing neurasthenic heart symptoms to an increased mobility of the heart. "These symptoms," says Braun, "as all other well-known heart symptoms of neurasthenics, are of a specifically neurasthenic nature, expressions of a constitutional neuropathy." Braun, therefore, wishes to eliminate the expression movable heart from clinical pathology. On the subject of cardioptosis, however, Braun says nothing.

After this short historical literary review, I would now like to communicate my own experience with this condition. Before doing this, however, it would be of advantage first to recall the normal boundaries of the heart, and, secondly, to answer the question, whether it is proper to speak of cardioptosis as a disease.

The relation of the deep or large (relative) heart

dulness, as well as of the superficial or small (absolute dulness), is illustrated by the following figure taken from Sahli's book[10] on Clinical Diagnosis: We see from this that the boundary of the relative dulness runs in a curved line from the upper margin of the left third rib about parallel to the boundary of the superficial absolute heart dulness outward and to the left, to assume a some-

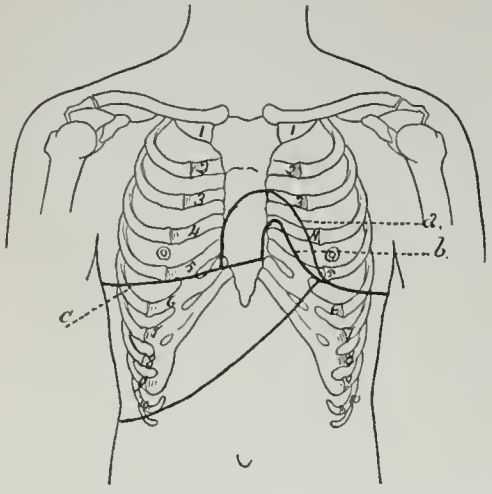

Fig. I.—Showing normal position of heart and liver. *a*, relative heart dulness; *b*, absolute heart dulness; *c*, liver dulness.

what more perpendicular course inside of the mammillary line and to end near the point where the apex beat is felt. Downward the heart dulness usually merges with that of the liver.

Normally, therefore, the relative heart dulness begins at the upper border of the third, the absolute heart dulness at the upper border of the fourth rib, whereas the apex beat is found in the fifth intercostal space to the right of the mammillary line.

Cases in which the heart assumes a position lower than that given above without being enlarged are considered as cases of cardioptosis. Is this designation "cardioptosis" pathologically justifiable? This question I must answer with a decided affirmative. Even if there are cases of cardioptosis that present no symptoms, as we will see later on, this is no proof that we do not have to deal here with an abnormal condition. Enteroptosis also frequently presents no symptoms, yet nobody disputes at present its classification as a separate disease. Cardioptosis has exactly the same right of recognition in pathology, as it may cause certain definite symptoms in a number of cases.

After these preliminary remarks I would like to enter upon a review of my own observations. I have carefully examined all my private patients during the last three months (October, November, December, 1902) for the presence of cardioptosis. During this time 926 persons (512 men, 414 women) were treated.

Among those treated there were twenty-two cases of cardioptosis, eighteen men and four women. The total percentage of cardioptosis among my patients amounted to 2.4 per cent. Taking each sex separately, it was 3.5 per cent. in the male and about 1 per cent. in the female sex.

I will now give the histories of a few of the cases of cardioptosis and present the rest of the cases in a table.

Case I.—Adolph, J. P., twenty-eight years old, has been suffering for many years from "nervous heart palpitation," but has otherwise aways been well. Appetite was always good, constipation was always present. Three months ago patient began to suffer from attacks of pain in the abdomen, accompanied with frequent vomiting, and occuring about once in two to three weeks. During the attacks the pains are so violent that morphine injections had to be given. Relative heart dulness begins at the lower margin of the fourth rib; apex beat lies between sixth and seventh rib; heart sounds normal, pulse 76. Liver dulness begins at the seventh rib and reaches to one finger's width above the navel. The stomach extends three fingers below the navel. Patient looks pale and emaciated.

Case II.—November 12, 1902—Charles D. H. C., forty years old, cutler, has never been seriously ill in his life, never smoked or drank much. Has been suffering from stomach trouble for about twenty years. About two hours after eating he feels bloated and nauseated. He would often expectorate several mouthfuls of water and then eructate gas and feel better. He lost about twelve to fifteen pounds in the last year, and weighs now about one hundred and fifteen pounds. He says that he has no ambition, suffers from melancholia, and always feels cold, especially at night. He has always eaten his meals in a great hurry. He suffers occasionally from heart palpitation, but is never short of breath, even after exertion.

Present Condition.—Heart: upper boundary of the absolute dulness begins at the sixth rib and runs parallel with it for 5 cm. to the left of the sternal line, and at the seventh rib for 5½ cm. The relative dulness begins at the lower margin of the fourth rib and follows in its outlines those of the absolute dulness. To the right it goes somewhat beyond the right sternal margin. Apex beat not plainly felt; heart sounds are loudest in the seventh intercostal space, and of normal quality. Stomach extends two fingers' width below the navel. Liver dulness begins in the seventh intercostal space, extending in the mammillary line to four fingers' width below the right costal margin.

Case III.—Robert A., thirty years old, commissioner, has always been well. He does not drink much, but smoked considerably up to four months ago. He has been complaining for some time of pain over the heart, which is more severe in the morning when he arises or whenever he runs. It is not very intense in character. Bowels are con-

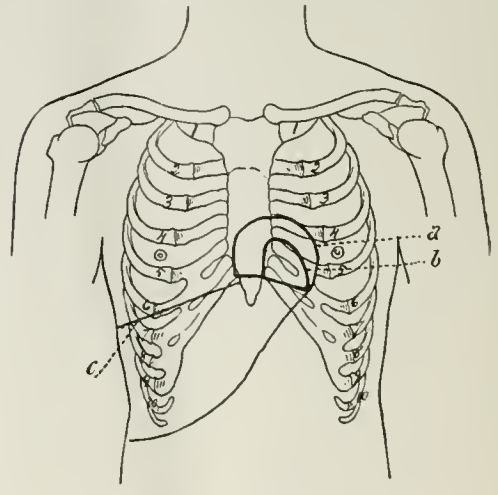

Fig. II.—Showing position of heart and liver in cardioptosis. *a*, relative heart dulness; *b*, absolute heart dulness; *c*, liver dulness.

stipated, appetite is good; patient sleeps well. He has been on a moderate diet for one and one-half years.

Present Condition.—Man of medium size, young looking for his age. Absolute heart dulness begins at the fifth rib, apex beat in the sixth intercostal space about 2½ to 3 cm. to the right of the mammillary line. If he lies on his left

side, the apex beat moves about 1½ to 2 cm. to the left of the mammillary line, if he turns on his right side, the apex beat disappears entirely and the absolute dulness appears to the right of the right sternal margin. Heart sounds are clear, pulse is 72. Absolute liver dulness begins at the eighth rib and extends in the right mammillary line three fingers' width below the the costal margin. The stomach reaches to about 3 fingers below the navel. The right kidney is movable in the third degree. Urine is negative.

Case IV.—December 3, 1902. Morris S. C. H., thirty-one years old, tailor, complains for two and one-half years of a feeling of oppression after meals and constipation. He cannot lie on his right side and consequently must lie on his left side; the dorsal position is the most comfortable. Absolute heart dulness begins at the fifth rib. Apex beat lies between the sixth and seventh ribs. There is slight heptoptosis, and the right kidney is movable in the first degree. Stomach extends two fingers below the navel.

TABLE OF THE REMAINING CASES OF CARDIOPTOSIS.

No.	Name.	Age.	Position of the Heart.		Position of the Liver.		Presence of Nephroptosis.	Principal Symptoms.	Remarks.
			Upper Boundary of Absolute Dulness.	Position of Apex Beat.	Upper Boundary.	Lower Boundary.			
1	L. D.	32	Lower border of 4th rib.	6 intercostal space.	7th rib.	3 fingers above navel.		Weakness, occasional palpitation.	Dil. vent.
2	C. R.	28	Lower border of 4th rib.	Indistinct. Lies below 5 intercost. space.	7th rib.	2 fingers below costal margin.		Neurasthenic symptoms. Occasionally vertigo.	
3	P. F.	27	Upper border of 5th rib.	6 intercostal space.	7th rib.	2 fingers above navel.		Weakness, vertigo.	Gastroptosis.
4	H. G.	58	Lower border of 4th rib.	6 intercostal space.	7th rib.	3 fingers above navel.		Weakness, palpitation.	Dil. vent.
5	J. P.	34	Upper border of 5th rib.	6 intercostal space.	7th rib.	2 fingers above navel.		Weakness, anorexia, constipation.	Gastroptosis.
6	M. Sch.	31	Upper border of 5th rib.	6 intercostal space.	2 fingers above costal margin	Navel line.		Grave anæmia, weakness, vertigo.	Pulse 56.
7	W. G S.	47	5th rib.	6 intercostal space.	2 fingers above costal margin.	1 finger above navel.	Ren. mob. dext.	Weakness; fulness, and tension in abdomen after meals.	
8	H. L.	30	Lower border of 4th rib.	6 intercostal space.	7th rib.	2-3 fingers below costal margin.		Weakness, vertigo, neurasthenia.	Pulse 72.
9	Mrs. Y. R.	35	5th rib.	6 intercostal space.	2 fingers above costal margin.	1 finger below costal margin.	Ren. mob. dext. 3 deg.	Weakness, palpitation.	Dil. vent.
10	Mrs. B. B.	33	Lower border of 4th rib.	6 intercostal space.	2 fingers above costal margin.	Navel line.		Dyspnœa after meals, Unable to lie on left side.	Anæmia, urine negative.
11	H. G.	34	Upper border of 5th rib.	6 intercostal space.	7th rib.	2-3 fingers below costal margin.		Palpitation, vertigo, fainting spells.	Neurasthenia.
12	H. B. I.	50	Upper border of 5th rib.	6 intercostal space.	7th rib.	3 fingers below costal margin.	Ren. mob. dext. 2 deg.	Weakness, vertigo.	Enteroptosis.
13	H. E. G.	56	Upper border of 5th rib.	Indistinct.	7th rib.	3 fingers below costal margin.	Ren. mob. dext. 3 deg.	Vertigo, insomnia, anorexia.	Enteroptosis.
14	Mrs. M. S.	35	Lower border of 4th rib.	6 intercostal space.	7th rib.	2 fingers below costal margin.	Ren. mob. ut. R. 2 deg. L. 1. deg.	Vertigo, palpitation, fainting spells.	Enteroptosis.
15	Miss J S.	24	Lower border of 4th rib.	6 intercostal space.	2 fingers above costal margin.	Navel line.	Ren. mob. ut. R. 4. deg. L. 2. deg.	Anorexia, constipation.	

Case V.—December 21, 1902. Samuel F., forty-three years old. Relative heart dulness begins at the upper margin of the fourth rib, absolute dulness at the upper margin of the fifth rib. Apex beat is noticeable 3½ cm. to the right of the mammillary line between the fifth and sixth ribs. If the patient lies on his left side, the apex beat is felt plainest 3½ cm. to the left of the mammillary line. If he turns on his right side, the apex beat is found 3 cm. to the right of the mammillary line. Stomach extends to nearly a hand's breadth below the navel. Liver begins at the seventh rib and projects two fingers' width beyond the costal margin.

Case VI.—December 21, 1902. Joseph L., thirty-seven years old, storekeeper, does not drink much, but smokes to excess. Ten years ago he worked very hard, especially late at night, and then began to feel very nervous and weak. He never had headaches and slept very well. He does not sleep so well now. Patient occasionally wakes up during the night with a feeling of oppression over the heart, is then unable to make any muscular exertion for a while (such as raising his arm, etc.) and is distinctly conscious of the beating of his heart, but does not experience any painful sensation. During these attacks he always suffers greatly from a sense of fear and of impending danger, and cannot lie on his left side. When he is attending to his business he never has palpitation of the heart, even when he mounts the stairs. He is often, however, short of breath. Patient is despondent and feels frequently like fainting and dying. He is constipated.

Present Condition.—Small heart dulness begins at the fifth rib; apex beat is situated in the sixth intercostal space. When he lies on his left side apex beat moves 3 to 4 cm. to the left; when he is on his right side, apex beat disappears. Stomach extends to three fingers' width below the navel. The absolute liver dulness begins at the seventh rib and ceases in the right mammillary line two fingers' width below the margin of the ribs. Pulse is 70, urine negative.

Case VII.—Julius C. H., twenty-eight years old, cigarmaker, has always been healthy, with the exception of a gonorrhœa five years ago. Family history is negative. Two years ago he began to complain of constipation and loss of appetite, as well as of a bloated feeling after eating. He never had palpitation of the heart and has never been short of breath. Climbing of stairs does not distress him.

Present Condition.—Upper boundary of absolute heart dulness begins at the lower margin of the fifth rib. Apex beat lies in the sixth intercostal space somewhat to the right of the mammillary line. Upper liver dulness begins one finger's width above the right costal margin. Urine is negative.

The remaining fifteen cases of cardioptosis are briefly summarized in the following:

Remarks—Etiology.—Emaciation, enteroptosis, and neurasthenia seem to play a part, but they alone are not sufficient to cause cardioptosis.

In women cardioptosis occurs much less frequently than in men, as we see in figures I and II,

whereas enteroptosis is much more frequent in the female sex. The explanation of this might possibly be found in the following: women usually wear corsets; these exert a pressure upward and downward, the former crowding the contents of the thorax upward, the breast serving as a supporting cushion; the heart is hereby maintained in its normal position.

Some authors have made a stooping position in working, writing, reading, etc., responsible for the development of cardioptosis. This cause is also more often found in the male than in the female sex.

Symptomatology—Subjective Symptoms.—If we peruse the clinical history of the above cases we shall find that nervous disturbances of the heart, as palpitations, attacks of vertigo, and occasionally inability to lie on the left side, are the principal symptoms in these patients. Very similar complaints are, of course, occasionally met with in people without cardioptosis, yet in patients affected with cardioptosis these symptoms are present in over half the cases, and must, therefore, be in some relation to this anomaly.

Objective Signs.—The relative, as well as the absolute, heart dulness usually begins about one rib lower than normal. On an average the large or relative heart dulness begins at the fourth rib, the small or absolute dulness at the fifth rib. The heart itself is not enlarged and does not show any sign of organic disease, the sounds being perfectly clear and normal. (See Fig. 2.)

Mobility of the Heart.—In a number of cases of cardioptosis I have examined the mobility of the heart in various postures and have usually found an increased mobility. Thus the distance of the apex beat from the point where it was felt plainest in the dorsal position, to the point where it was found in the left lateral position was 3 to 5 cm. In the right lateral position the apex beat often disappeared altogether, and the absolute heart dulness could be demonstrated to the right of the sternum.

Cardioptosis and Ptoses of Other Organs.—In nearly half the cases of cardioptosis a general enteroptosis is found, and in all cases a more or less well-marked degree of hepatoptosis. This point seems to have escaped the attention of most observers. It seems at first sight singular why in all cases of cardioptosis a hepatoptosis should be present. We can, however, easily explain it. Descent of the heart necessarily causes descent of the diaphragm. The latter condition, therefore, will cause the hepatoptosis. We might invert this proposition and see whether all cases with hepatoptosis are associated with cardioptosis. This, however, is not the case, as I can assert from a large experience with this subject.

Prognosis.—Cardioptosis does not endanger life, and the subjective symptoms caused by it may be alleviated or entirely removed.

Treatment. — Improvement of nutrition and strengthening of the nervous system must be considered the main objects in treating cardioptosis. The first is accomplished by a generous diet, the latter by methodical strengthening of the body by means of cold ablutions, moderate gymnastic exercises, and sojourn in the open air. Beside these two points any factor that tends to affect the position of the heart should be avoided. The patient will, therefore, have to be told not to remain too long in a stooping position. During sleep it might be advisable to place the head and thorax as nearly horizontal as possible or in a position only slightly elevated. Means for direct support of the heart are hardly indicated. A suitable support might be applied at the beginning of the lower third of the thorax, exerting an upward pressure. A woman's corset with a left breast pad might serve as an example. I have, however, no personal experience with this procedure and will not discuss these mechanical means any further.

Encouraging words, and occasionally a sedative like bromide of soda, tincture of valerian, etc., are sometimes necessary and—in patients who are excited over their condition, or who have been worried about their health—are often of the greatest value.

THE PATHOGENESIS OF DIABETES.*

By HENRY S. STARK, A.M., M.D.,
NEW YORK.

In the absence of incontrovertible pathological knowledge of the origin of diabetes mellitus, and in our zealousness to locate the lesion, few organs have escaped the watchful eye of pathologist and of clinician. Thus it is customary to attribute the lesion, in individual cases, to the liver, the pancreas, the nervous system, the gastrointestinal tract, the kidneys, the ductless glands, and the muscularis. Naturally, I refer to clinical diabetes, and not to functional, transitory, or experimental glycosuria. It seems, however, to be agenerally accepted belief to-day that the liver, or the pancreas, is the organ most frequently involved; at least the trend of most medical minds is in that direction, or else, like all things mortal, the pursuit of the medical sciences is influenced by style and vogue. For a glance at the literature of the subject will make it very clear that these two organs, at present, hold the center of the stage, and that the heterogeneous theories that formerly held sway have been relegated to an oblivion.

This diversity of opinion regarding the true site of the lesion demonstrates very clearly that our knowledge of its origin is, at best, provisional; but it is a consolation to know that it is not altogether barren of well-established data, truly of a negative character, but sufficient to justify a reawakening of intelligent interest in its pathogenesis.

The liver was most frequently referred to as the seat of the lesion, because of its physiological function in the production of glycogen. For a long time it was believed, and is even yet, that a disturbance in this sugar-conversion function, either an arrest or an increased activity in it, caused a glycosuria. The glycosuria was thought to be due to an unusually abundant supply, or to a rapid absorption of sugar. In the former instance it meant a hasty

*Read before the February meeting of the Harlem Medical Society.

circulation through the liver, in the latter instance, a diminished consumption of sugar in the system.

While there are many *a priori* arguments which might be ranged up in support of this view, that an unstable equilibrium of the glycogenic-function is the decisive factor, nevertheless, in the absence of more convincing evidence, especially of a post-mortem nature, we are only thrown back upon hypothetical considerations. For if the glycogenic function of the liver controls the ultimate distribution of the ingested carbohydrates, and is responsible for their transportation and ultimate distribution into the circulation, it stands to reason, that in the course of our daily existence, there must frequently occur disturbances of this function; and yet how comparatively rarely are these followed by glycosurias. Disturbances in the functions of other organs manifest themselves in no uncertain manner. Why it should occur in some instances and not in others, or why in the same subject at one time and not at another, are matters of mere conjecture, and the circumstance furnishes an argument against the claim that diabetes depends upon a disordered glycogen-function.

Further, it is known that lesions of the liver occur, accompanied by a complete destruction of hepatic tissue and by a perversion of all its physiological functions, and yet in few instances have these changes been followed by diabetes; and conversely, in many cases, of death from diabetes, the post-mortem appearances of the liver were entirely normal.

The origin of glycogen and its subsequent conversion into glucose are well established normal functions, and yet physiologists tell us that we cannot account for the manner or the influence by, and under, which this metamorphosis takes place, and I firmly believe that as soon as this unknown quantity, be it ferment, enzyme, or other product of vital activity, is discovered which effects this transformation of ingested carbohydrates, just so soon will the mystery of the evolution of sugar in blood and urine be cleared up. At least those cases of diabetes which are amenable to treatment by the withdrawal of carbodyhrates. One circumstance of interest in this connection suggests itself. Is this unknown quantity the poisonous product of bacterial growth? Not at all improbable. Numerous ptomains have been isolated as a result of the putrefactive processes of albuminous matter, *e.g.* indol, skatol, peptoxin, and the list is constantly swelling. Why not ptomains from the putrefactive processes of carbohydrates or of fats? These intermediate products, above cited, in the process of proteolysis strongly suggests the probability of intermediate products of amylolysis and of lipolysis. Indeed, according to some investigators, the existence in blood-serum, of certain enzymes, is indubitable. Experts have found in diabetic urine, elements of a decidedly toxic nature; so much so, that the urine of diabetics in the last stages of the disease, and during coma, is now acknowledged to possess marked toxicity. This phenomenon has been elaborated *in extenso* by animal experimentation.

If now it be admitted that, as a result of perverted glycogen-function, a toxin be produced, its mode of action would be apparent. It would naturally exhibit a predilection for the nerve centers and the vasomotor center, and, as a secondary consequence, the natural deposition of glycogen by the liver, would be retarded or otherwise altered, and it would be eliminated by some other emunctory, such as the kidneys. The inference drawn from the question of hepatic toxicosis, is, that the quantity of glycogen stored up in the liver is controlled by nerve influences. This hypothesis is not at all unreasonable, and has its analogue in disorders connected with other organs. For example, the hectic phenomenon, which is a concomitant of suppurative processes, is, as I have attempted to prove in a previous paper, also a nerve-center toxicosis.

The glycogen-function then, pure and simple, cannot be held responsible for the disease, and this statement is further corroborated by the fact that in other organs and parts, such as the kidneys, the muscles, the brain, the testes, and certain embryonic tissues, this same function is demonstrable and, therefore, were glycosuria solely dependent upon it, diabetes would be a more frequent incident in diseases connected with these parts.

Nevertheless, there are some cases of diabetes, which cannot be accounted for in any other way than on the basis of a hepatic origin. Especially interesting in this connection, are the results of a collective investigation of the origin of diabetes from hepatic sources. Numerous observers have investigated the matter and reports indicate that a positive result is not even obtained in 50 per cent. of hepatic disorders of all kinds. Strauss, for example, found sugar in only two out of thirty-eight cases, and in his collection of 107 cases from literature, he found positive results in only fourteen.

Still another theory in explanation of the hepatic origin was, that the ingested carbohydrates were too rapidly converted into starch and were imperfectly oxidized. With our clinical experience of to-day, this theory is just as untenable. For we are reminded of the fact that healthy individuals can consume large quantities, say one hundred grams, daily, without any of it appearing in the urine. Secondly, were a glycosuria dependent upon an over-indulgence and consequent non-assimilation of sugars and starches it would, of necessity, cease directly these foodstuffs were eschewed. Yet what is our clinical experience? We constantly observe diabetics whose urine is never free from glucose, despite an exclusive diet of animal food, and others again whose urine contains proportionately more glucose than is ingested as food. As offsetting this last view of the causation of diabetes, came the theory of Bernard. His experiments led to the conclusion that glycosuria could follow a paralysis of the vasomotor nerves of the blood vessels of the liver. But the objection was raised that experimental or temporary glycosuria is not true diabetes. We are not justified in accepting Bernard's conclusions as constant truths, because experience has taught that results obtained experimentally in the animal world cannot always be duplicated, clinically, in the human economy. One circumstance, however, remains unquestioned, and that is, that the glycogen-function of the liver is influenced by the central nerve apparatus in no small degree. As a matter of fact, anatomists have even gone so far as to trace the course of influence from brain to liver, all through the various nerve elements, detailing the individual nerves involved.

If now we admit, for argument's sake, that the glycogen-function depends upon—or rather, is considerably controlled by a ferment or enzyme formed in the liver, then the so-called hepatogenic variety of diabetes would mean a disease of the liver, most likely the ultimate structures, the hepatic cells, caused by a nerve or vascular derangement, resulting in an excessive formation of sugar from glycogen, and manifesting itself in a pathological glycosuria. It would mean that liver diabetes owed its origin to an overproduction of glucose through the inter-

mediary of a biochemical agent which prevented its complete oxidation in the body.

In this latter connection it is a matter of more than passing interest that the disturbance in the carbohydrate metabolism of diabetics is not peculiar solely to glucose, but is common to most all carbohydrates, such as lactose, levulose and the pentoses. The discovery of this chemical fact was used as an argument that the disease could depend upon a glycolytic ferment alone, else why were not lactosurias, and pentosurias accompanied by the same clinical features as glycosurias were? The possible appearance of the pentoses in the urine is a point of considerable clinical and diagnostic interest, for the reason that these agents reach positively toward Fehling's solution. Cases of pentosuria accompanied by pathological phenomena are not of unusual occurrence, and it therefore behooves the clinician to be able to distinguish between this type of perverted carbohydrate metabolism and diabetes. The method I employ is Bial's modification of Tollen's orcin test,* and is readily made if a stock solution be kept on hand.

Other theories of the pathogeny have been proposed, with the liver as the central figure, but these lack confirmation and are untenable in the light of our newer knowledge of certain physiological functions. Thus it was thought, for a time, that diabetes was dependent upon a diminished alkalinity of the blood of the portal circulation. It was likewise believed, at one time, that diabetes resulted from an over-stimulation of the hepatic nerves; at another time it was thought that an unusual rapidity of the portal circulation was at the bottom of the disease in question.

In a general way it may be claimed that the importance of the liver in the causation of diabetes cannot be determined until we come in possession of more reliable data of the sources of the glycogen, and of its subsequent disposal in the healthy organism. We must know more of its general chemical behavior, of its derivation from foodstuffs other than carbohydrates, of its occurrence in parts other than the liver, particularly its occurrence in leucocytes, protoplasm, and in lymph.

The pancreas is at present attracting most attention as the offending organ in diabetes. Only until comparatively recently the subject of diseases of this organ was a *terra incognita*, into the domain of which few pathologists ventured. To-day the influence of the organ in the causation of this disease cannot be gainsaid. The physical properties of the pancreatic juice, especially its triple perhaps manifold, physiological function on alimentary substances, are matters of much concern in the determination of the origin of diabetes. In estimating the importance of this organ, as a pathological factor, I would call your attention to the following fundamental facts as a preface to what follows: (1) The pancreas, like the liver, is a glandular structure, made up considerably of globules, which consist of cells secreting a fluid. (2) The physiological action of the secretions is in some respects analogous. (3) The orifices into the duodenum of the common bile duct, and of the duct of Wirsung, are in juxtaposition, as though nature intended their secretions to be adjuvants. (4) In many animals this arrangement of the points of exit of these ducts is similar, relatively to that in the human species. (5) The time of the greatest discharge of the normal secretion of liver and of pancreas, is almost synchronous. (6) The ultimate cells of both organs furnish digestive ferments. (7) In certain vertebrates that have no pancreas the functions, which should be performed by the latter, seem to be performed by the liver. (8) In certain invertebrates which seem to have no liver, or rather no formation of bile, a structure seemingly analogous to the pancreas appears to be the organ of digestion. (9) Interference with the glycogenic function of the liver or of the pancreas may be followed by glycosuria.

These points of analogy between liver and pancreas strongly suggest the possibility that their physiological functions are reciprocally related, that their mode of action on ingested matter is, for all intents and purposes, identical in some particulars, that in the absence of one organ, or in its failure to perform its work, the other is called into requisition, that the glycogenic phenomenon is subject to the influence of the pancreatic juice to no small degree; in short, the conclusion is almost inevitable that *the pancreas is a supernumerary liver*. We are confronted here, not merely with a theory, but with a material condition, and observations from animal experimentation lend color to this view.

Thus it is known that diabetes may follow a complete extirpation of the pancreas in man and in many animals; in such depancreatized animals it has been satisfactorily demonstrated that the glycohæmia resulted not from a diminished consumption of normal sugar but from an increased formation of sugar; showing that the pancreas controls to some extent the formation of sugar by the liver. Whether it does so through the agency of some chemical substance of an internal secretion, has not yet been definitely ascertained, but such a secretion is within the range of all possibility. Lepiné, experimenting in this direction, claims that this substance is an enzyme, derived from leucocytes and formed within the pancreas by a transformation of diastase. In 1900 Lepiné and Boulud announced that they had succeeded in extracting from the urine of diabetic patients a crystalline substance which produced glycosuria when injected into the jugulars of dogs or under the skin of guinea-pigs. After further experimental research, the same observers announced that this chemical substance inhibited glycolysis in the blood and was destroyed in the pancreas; which organ appeared to possess antitoxic potency. The exact nature of this hypothetical substance could not be determined, nor could the conditions of its existence in the economy be ascertained. When these circumstances are revealed, a better interpretation of the effects and actions of this substance will obtain.

One stubborn fact, however, is settled, that if there exists such a distinct pathological entity as a pancreatic diabetes, the diabetic juice is not concerned in its production. For when this fluid is diverted from its natural channel, by means of an artificial fistula, it does not necessarily follow that a glycosuria will make its appearance. This experiment has been made time and again, proving that diabetes of pancreatic origin must depend upon some other feature connected with the physiology of the pancreas. Another circumstance of an experimental nature to establish such a relation, is the failure to produce diabetes artificially by anything short of a total or almost total extirpation.

*The test solution is the following: one and a half grams of orcin is dissolved in 500 grams of fuming hydrochloric acid, to which is then added twenty-five drops of a ten-per-cent. solution of ferric-chloride. To make the test, two or three cubic centimeters of urine are added to four or five cubic centimeters of the reagent. Heat the mixture until bubbles begin to rise: should flakes be precipitated or the mixture turn green, pentoses, are present.

If only a small portion of the pancreas remained behind, glycosuria would not make its appearance. Probably because some structural cells which secreted the suspected enzyme, were still active in converting or oxidizing carbohydrates. In other words, the portion of pancreas remaining, was sufficient to fulfil the glycogenic function in disposing of ingested carbohydrates. The ultimate disposal of this internal secretion is accounted for on the presumption that it finds a way into the lymph-stream and so into the circulation. Experimental evidence of this course is not wanting, for the injection of lymph from the thoracic duct into the vein was followed by glycosurias of varying intensities. The question then of an internal secretion of the pancreas, or the existence of an enzyme, or of an inhibitory glycogenic substance is still in the experimental stage. At this juncture absolute proof of its existence is still forthcoming.

However vague our state of mind may be on the question of an association from a purely physiological aspect, between diabetes and the pancreas, the veil of mystery is far from being cleared up by a consideration of the anatomical studies of this organ.

The work of Langerhans in 1869 on the histology of the pancreas, in which he described groups of peculiar cells, lying between the acini, acted as a stimulus to extensive experimental research and clinical observation. Recently these so-called "islands of Langerhans" became the object of animal experimentation, with a view to ascertaining their nature and physiological function, and their province in the production of glycosuria. As supplemental to this material, a limited clinical experience, reinforced by post-mortem findings, is proposed by some competent authorities, to support the contention of an interrelationship between this organ and diabetes. In 1877 Lancereaux claimed that post-mortem evidences seemed to establish a connection between the pancreas and a certain type of diabetes. The type in question was a severe form of the disease, was accompanied by rapid loss of strength and flesh, a glycosuria which was rarely amenable to treatment, persistent thirst, epigastric pain, and death. The anatomical appearances of the pancreas coincided with those of an atrophy of the organ or of its duct, or a fatty degeneration, a necrosis, a sclerosis, or a cystic degeneration. Even calculi, abscess, and carcinoma were distinguishable, post-mortem.

There was, thus, no characteristic and exclusive lesion, associated with this type of disease, which could be held accountable for the symptoms.

Certain French investigators suggested that these islands secreted a fluid peculiar to themselves, which was directly concerned with the appearance of the glycosuria, and asserted that when extensively involved, diabetes was certain to follow.

Hauseman of Berlin reported 40 cases of death from pancreatic diabetes, of which 36 presented evidences of atrophy of the pancreas. Williamson collected from literature 100 cases of diabetes in which the pancreas showed morbid changes. Of these 100 cases, 39 presented atrophic changes. Hauseman also collected records of 72 cases of death from pancreatic diabetes, of which number atrophy was noted in 38 cases. Weichselbaum and Stange, in 18 cases of death from pancreatic diabetes, found atrophy of the organ in 17.

These figures indicate that atrophy of the pancreas is found in many cases of death from diabetes, and this fact raises the supposition that the atrophy in question may have been merely a part of the wasting of the whole body, which is so common in this variety of the disease. For we might with equal propriety attribute the disease to an atrophy of some other organ, which was coincidentally involved in the general progressive atrophy. In diseases other than diabetes, atrophy of the pancreas is not uncommon. Taking one hundred consecutive cases of death from other general diseases, it would be natural to find post-mortem changes in the pancrease in a certain percentage of them.

Such pathological evidence, as I have just quoted, is not conclusive, for it raises a doubt as to whether the pancreatic lesion itself was really the decisive one, or whether it was merely an incident in the general morbid process. Therefore, until a specific lesion is proven beyond peradventure, the claim of a pancreatic origin of diabetes is only suppositious.

Clinically, it appears more probable; but it will always remain a matter of fact that many cases of pancreatic disease, even of a chronic and severe nature, will run a course unaccompanied by a glycosuria, and conversely there must occur many cases of diabetes without pancreatic involvement. However, sufficient anatomical material has been collected to furnish a working hypothesis in this line of investigation. Included in this fund of anatomical knowledge, the following facts eclipse all others in importance. Firstly, the islands of Langerhans possess a marked resistance to certain morbid processes involving the pancreas; secondly, certain other morbid processes exhibit a predilection for these islands, and, thirdly, their tendency to destruction in certain types of diabetes justifies the suspicion that they have distinct functions. These distinctive anatomical features constitute a starting-point, and plainly indicate the direction which future investigations must take to be productive of tangible results.

The view of E. L. Opie, as expressed in two articles which appeared in the *Journal of Experimental Medicine*, takes the form of a confirmation of the generally accepted theory that in a definite type of diabetes, appreciable lesions take place in the parenchyma of the pancreas. Other exponents of this theory, such as Hoppe-Seyler, Hauseman, and Feiner, have described the anatomical changes of the pancreas, detailing the minute anatomy of the diseased part

According to Opie, the pancreas in diabetes is the seat of a chronic inflammation, affecting the acini, rather than the lobules, and accompanied by a hyaline degeneration of the islands of Langerhans. When the invasion and degeneration of these islands become extensive, diabetes results. His reports indicate that in one out of eleven cases of interlobular pancreatitis diabetes was present, while in interacinar pancreatitis two out of three cases were diabetic. He concluded that the microscopic findings established a relation between diabetes and a lesion of these islands. This view of the origin of diabetes, even from a conservative standpoint, is not beyond the pale of just criticism. The first objection that would suggest itself, is that the cases with positive results are too few to allow of any generalization. It is illogical to draw definite conclusions in pathology from scanty material. One might reasonably suspect that the association of pancreatitis and diabetes in an individual case was merely accidental. Such a contingency is not unlikely. If the relation between the two conditions were one of cause and effect, their simultaneous occurrence should be a matter of course, which it is not for a number of cases of chronic interstitial pancreatitis without diabetes, have been reported in the transactions of several pathological societies. Another moot point against such a relationship, is the well-

known fact that in certain advanced cases of atrophic liver cirrhosis, a concomitant interstitial pancreatitis, even involving the islands, is not uncommon.

An important event, which has a distinct bearing on this matter, is the peculiarity of the pancreas to self-digestion *intra vitam et post-mortem*, and thus to effect changes in its structure that may mask the autopsical findings.* The fact that lesions in the islands of Langerhans have been accompanied during life by glycosuria does not yet explain the *modus operandi* by which the diabetic phenomenon makes its appearance. Pathological processes of various kinds and of different and distant organs, have been preceded, accompanied, or followed by glycosuria, and yet in most instances to claim that this sequence was anything more than coincidence would be considered extravagant. The bare recital of a few of the diseases which have been reported to be associated with diabetes, proves the point. Among such are the following: exophthalmic goiter, tabes dorsalis, hypertrophic, and atrophic liver cirrhosis tumors of the vagus nerve, inflammations of the posterior columns of the cord, anterior poliomyelitis, affections of the medulla, and of the adrenals. All of these have been confirmed by post-mortem examinations. When we take into consideration the multiplicity of organs and parts which have been at various times associated with diabetes, we cannot avoid the conclusion that a claim to establish a common pathologic origin between them can not be confirmed by cumulative or autopsical evidence.

The study of those two anomalous types of pathological glycosuria, hæmochromatosis, of Von Recklinghausen, and "bronzed diabetes," has not shed much light on the question of the influence of the pancreas in their production. French writers, who have paid considerable attention to these morbid processes are doubtful whether these unusual lesions are entitled to be classified as special pathological entities, or whether the pigmentary cirrhosis of liver or pancreas or both, was only an incident in the course of the diabetes.

Anschütz collected from literature over twenty-four cases of *diabète bronzé*. Out of eighteen in which the pancreas was examined microscopically, fifteen showed evidence of a chronic interstitial pancreatitis.

In the recorded cases of hæmochromatosis, it was noted that diabetes followed in the advanced stage of the former. There is however, reason for believing that this rare condition is really a sequence which follows in the wake of a general disturbance of the cardiovascular system, as it is now acknowledged that an arteriosclerosis frequently accompanies diabetes, and that this very sclerosis of the vessels may be followed by secondary changes of a similar character in the structure of the liver, the pancreas, and of the kidneys. How a hæmochromatosis may lead to a cirrhosis of the liver or pancreas is readily understood, but how it should cause diabetes is not so easily explained. The mere deposit of iron pigment, derived from the hæmoglobin about the blood vessels, and in the ultimate cells of the parenchyma, would not in itself produce a glycosuria. If it did we would just as likely find a copious excretion of iron in the urine.

The pathogenesis of the so-called bronzed diabetes is delusive as far as its connection with the causation of glycosuria is concerned. There is ample clinical and autopsical evidence to prove that a pigmentation is also connected with exophthalmic goiter in over 10 per cent. of cases and that a generality of such cases are followed by diabetes; and the same holds true of the adrenals. That is to say, there are on record cases of bronzed diabetes, which, on post-mortem examination, disclosed histological changes in the suprarenal organs, demonstrating that an "adrenal pigment diabetes", so to speak, is within the range of possibility. It is worthy of comment, in this connection, that pigment diabetes is frequently associated with lesions of the ductless glands, the very organs which are concerned in producing retrogressive changes in the blood; the most frequent of which are various stages of degeneration and discoloration of the red-blood globules. This observation favors the idea to which I have alluded in a previous part of this article, that the pancreas, and the ductless glands as well, the thyroid, spleen, and adrenals, secrete under normal conditions a substance which destroys toxins, and that when this power is inhibited, such toxins accumulate in the system, and by antagonizing the sugar-destroying substance in the blood cause a glycosuria.

Some time ago Blum, Herter, and others made an experimental study of the influence of local applications of the active principle of the suprarenals, adrenalin, in the production of glycosuria. This substance was employed subcutaneously, was injected into the veins and into the peritoneum, and was painted on the surface of the pancreas. All of these experiments upon animals with adrenal chloride were quickly followed by a glycosuria of a few hours' duration.

Similar local applications to the spleen, the kidneys, and the liver were not followed by a glycosuria. Believing that this phenomenon depended upon a failure of the pancreatic cells to take up the oxygen of the blood, Herter studied the conditions further, with a view of establishing this supposition. He painted the surface of the pancreas with several reducing substances, in order to deprive them of their oxidizing function, whereupon he discovered that in all instances, glycosuria supervened. When, however, the adrenalin was oxidized and thus deprived of its reducing power, the glycosuria failed to make an appearance. He, therefore, felt justified in deducing the conclusion that an interference with the oxidizing functions of the pancreatic cells lay at the root of the glycosuria.

This conclusion, it seems to me, is too sweeping in its claim, and is unwarranted by certain well-known facts in connection with experiments upon animals. Why the mere painting of a small patch of the surface of the pancreas with a doubtful fluid should be responsible for a glycosuria, while the same phenomenon should fail to obtain when a large part of the pancreas is involved in a pathologic process, or is experimentally removed, are matters which are not yet reconciled by the explanation offered.

Again, as Meltzer has argued, the glycosurias in Herter's cases may just as reasonably have resulted from reflex action. So, likewise, the trauma embraced in the operative procedure may have occasioned it. Far less violent and insignificant influences than those included in the experiments in question, have been known to be responsible for a glycosuria, of a transient nature. When psychical influences, such as fright or shock, or the mere inhalation of a gas, or the ingestion of a simple drug, can cause a glycosuria, why should we be surprised to find the same phenomenon after operative measures of greater or lesser severity. I therefore believe we are justified in rejecting Herter's theory as unproven and unsupported by sufficient scientific data.

The theory of a bacterial pathology, always

*Opie himself acknowledged that this self-destructive capacity of the organ "prevented satisfactory study of the lesion."

fascinating, is not without its advocates, as would be expected in these days when King "Germ" occupies the throne, influencing all medical thought and shaping the course of all medical research. There is, however, no foundation, neither in fact nor in theory, for such a claim. No microscopic findings, just a few clinical facts, and these immature and inconsequential. Still it is always the part of wisdom to be reticent in our prophecies concerning the future possibilities of bacteriology, lest our most sanguine claims of to-day become blasted by the revelations and counter-claims of to-morrow.

Current events seem to indicate that the morbific element is a chemical agent rather than a microorganism. An agent produced by chemical changes, somewhere along the digestive tract or its accessory organs and resulting from a perverted metabolism of carbohydrates. Such an inference would properly mean that diabetes is a disease caused by an autointoxication. A very plausible theory, indeed, when we take into consideration the established fact that numerous toxins are continually generated in the gastrointestinal tract, and are destroyed, or rendered innocuous, under normal conditions. But directly this destructive or inhibitory faculty ceases, or is dimimished in power, the gastro- and enterotoxins make their presence felt in anatomical changes accompanied by functional disturbances of the parts involved. It is believed that the ductless glands, such as the thyroid, spleen, adrenals, have an internal secretion of their own, as alluded to in a previous part of this article, which destroys these toxins through the avenue of the vast lymphatic system, and that an impairment of this property of these glands is followed by well-marked and characteristic types of disease, not the least important of which is diabetes.

It is not the purpose of this article to discuss the many ways in which an excess of sugar may make its appearance in the urine, experimentally; transient glycosurias, unaccompanied by the classical symptom syndrome, is *ex parte* to the matter under consideration. Such artificial glycosurias, whether of liver, pancreas, kidney, or brain origin, whether produced surgically, mechanically, or chemically, are not accompanied by a polyuria, polydipsia, and a progressive loss of strength and flesh Included in this category is "phloridzin diabetes," which is a misnomer, a more appropriate term being a nephritic, glycosuria, as it is caused by an irritation or mild inflammation of the renal epithelial cells or of the interstitial tissue; in other words, an acute nephritis, in which the renal epithelia have lost their power of restraining the excretion of sugar by the urine. As a proof of this, Ehrlich cited by Strümpel, claims a glycogenic degeneration of the loops of Henle, the epithelial cells of which were found, chemically, to contain glycogen.

In reviewing the facts underlying the theories embodied in the substance of this communication, the following salient features are self-evident: (1) The exact truth of the pathology ofdiabetes is not known. (2) There are no acknowledged and constant, anatomical appearances of liver or of pancreas, associated with diabetes (3) There are no characteristic lesions in any other organ (4) An impairment of the physiological functions of the ductless glands may be at the root of the disease. (5) Artificial glycosuria is not diabetes. The facility with which this phenomenon can be elicited, implies its insignificance as a pathologic factor. (6) As far as can be ascertained from competent sources, there is hope that the vacuum in our knowledge of the nature of diabetes will soon be filled.

Clinical Department.

A CASE OF ACUTE DILATATION OF THE RIGHT SIDE OF THE HEART.

By P. P. M. JORGENSEN, M.D.,
KENOSHA, WIS.

On February 20, 1903, Dr. W. R. Cheever and myself were called to see a patient who was thought to be dying. When we reached the house we found a woman reclining in a rocking chair. She was unconscious and breathing very loudly and with difficulty. With each expiratory effort a profuse frothy discharge would escape from both mouth and nose. The pulse was 72 per minute, regular and of fairly good quality. She was a woman about five feet three inches in height, weighing 180 pounds. From members of the household we learned the following history: A week ago she had been visiting a neighboring city, and when she was about to return home she came near missing her car and ran as fast as she could for a short distance to catch it. After she boarded the car she was so out of breath that she felt actually sick from it. During the week she attempted to do a little washing, but the effort caused her to pant so for breath that she gave it up. On the day of our visit she prepared the dinner for the family as usual, and in the afternoon walked a short distance to the business portion of the city to do some shopping. She returned home and climbed the one flight of stairs to her flat, but was so out of breath that she had to drop into a chair immediately, and instead of being eased by the rest, the breathing rapidly became more labored and she very soon became unconscious.

Auscultation of the chest revealed the fact that both lungs were full of fluid, and the frothy fluid coming out of the mouth in large gulps with each expiration, showed that it was being produced rapidly. During the fifteen minutes from the time we reached the house until the woman was dead the pulse at the wrist remained fair in quality, but gradually grew slower and weaker as the respirations became less frequent. So from the time the woman started to mount the stairs, apparently in her usual health, until the time we left the house after she was dead, not more than three-quarters of an hour had elapsed.

It is needless to say that the heart stimulants, nitroglycerin, strychnine, and digitalis, which we administered, had no appreciable effect.

TUMOR COMPLICATING LABOR.

By GEORGE W. SQUIRES, M.D.,
EAST AVON, N. Y.

Mrs. B., age twenty-seven years, was in labor with her second child, August 10, 1902. With the first gestation, five years previous, there was much trouble from nephritis and albuminuric dropsy, so exaggerated that the body was twice its natural size; the urine was scant, and, on boiling, semi-solid. The vulva was enormously distended with serum, but with a mixture of epsom salts, rhubarb, and licorice powder, in drastic cathartic doses, the condition was relieved. Labor at the seventh month came on without indication, and the threatened convulsions subsided with the advent of confinement. The thought of a repetition of this terrible experience was a horror to the woman when she again found herself presumably pregnant. I saw her in the fourth month, and the secretions were normal, the woman coming to her accouchement in the best of condition. Within four hours of the commencement of pain the child was born in the

most normal fashion. There seemed to be a hitch in the third stage, however, for while there were strong pains, the after-birth failed to appear, even though Credé's method was employed; on making an examination I was surprised to find the vagina filled with a large, round, smooth, tense tumor, that, on careful manipulation, I found to be attached to the rectal aspect of the canal and exceedingly sensitive to touch. With a few whiffs of chloroform the patient allowed of better examination, when I found the placenta ready for expulsion, but its way debarred by the tumor. Under deeper anæsthetization I succeeded in getting my hand past the tumor, grasping the placenta, and with strong traction and twisting motion elongated and brought it by the tumor, when the womb closed down and the labor concluded ideally with the exception of the something in the vagina. This had appeared within thirty minutes, for between examinations not more than this time had elapsed, and it was certainly not there a few moments before the birth of the child. On the conclusion of the labor, I was hurriedly called to attend another woman in confinement. The tumor was still there the size of a large orange, but there being no hemorrhage and the woman saying she felt strong, I hastened away to the new case, leaving a good nurse in attendance. Within two hours the husband came in great agitation, saying his wife was in "great pain and straining harder than when she had the baby." As I could not leave a woman in the second stage of labor I sent a messenger to another town for a physician, gave the husband some tablets of Tully's powder, and hurried him home to administer them to his wife. In about four hours I was able to visit the woman and found everybody, including the nurse, asleep. The messenger had been unable to find a doctor, and the woman becoming comfortable after two or three tablets, they all turned in for rest. This tumor, which was probably a hæmatoma, disappeared, after several weeks. There was no fever, sepsis, or abnormal symptoms following, and the woman made a good recovery. There was no shock on the appearance of the vaginal tumor, though it must have been filled with blood. The labor being practically bloodless partially accounted for this. The severe after-pains were probably caused by this body in the vagina. The seat of pain, as afterward described by the woman, was in the rectum, as though the bowel was being torn out, and she said it was more painful than labor pains. Had this tumor come prior to the birth of child, it would have been impossible to bring the child out without rupturing the tumor, when there must have been a dangerous bleeding. I have been unable to find any literature touching these cases and their treatment.

On Heat-stroke.—Andrew Duncan discusses preventive measures for heat-stroke in the tropics, which include diet, and protection of the head, the eyes, the spinal cord, and the body in general. As to color, orange red has been found to be the best to ward off sun-stroke. The author recommends lining the helmet with orange-red flannel, having a similarly colored pad sewn into the inside of the khaki coat at the back and to wear an orange-red shirt when on the line of march. As to curative treatment, the patient, on the occurrence of heat-stroke, should be moved into the shade when possible, cold water be poured on his head and neck, and ammonia applied to his nostrils. The douche must be repeated until a favorable effect is produced. A turpentine enema should be administered, and a large mustard-plaster applied to the chest. If convulsions occur, a few whiffs of chloroform are indicated. In Italy, in cases of direct heat-stroke, the administration of a solution of trinitrine (1–1 000) twenty drops to water 4,500 minims, every quarter of an hour until the complete disappearance of the symptoms, has been found successful. Venesection has been advocated by some practitioners, but the author has never ventured to try it. His final advice to any one who has once suffered severely from heat-stroke is not to return to the tropics.

The Disadvantages of Ventrofixation.—Gradenwitz discusses the topic from the standpoint of observations made on his own material and that reported by others. While he admits that the operation affords the surest means of relieving the disorders attendant on retroversion, he believes that the benefit is but temporary and is sure to be followed by disturbances worse than the original trouble. In addition to the ever-present danger of hernia associated with this as with all laparotomies there is the risk of intestinal obstruction through the new-formed suspensory ligament, the interference with subsequent pregnancies and, lastly, the fact that in most instances a state of chronic metritis is set up which remains obdurate to the most persistent and careful treatment. Whether this state is brought about through the interference with uterine drainage due to the altered position of the organ, to local changes in nutrition caused by the presence of the sutures, or whether the perimetritic irritation leads to secondary metritic changes, is uncertain, but the fact remains that both subjective and objective evidence of such a condition is not wanting. As a substitute the author prefers the Alexander operation with the addition of a posterior vaginal section for the breaking up of adhesions, etc., in complicated cases. After the menopause vaginal fixation must be considered.—*Centralblatt fur Gynakologie.*

Corneal Burns.—E. M. Marbourg says that the treatment immediately following the removal of any offending substance or its neutralization (as alcohol followed by a cocaine solution for carbolic-acid burns, weak vinegar for lime, etc.), is that of the instillation every half hour of olive oil, preferably the heavy green oil. This gradually insinuates itself beneath the burned tissue, and as it does so also protects the living tissue beneath. In about twenty-four hours it should be discontinued, and a mild europhen or aristol ointment substituted until the eye has recovered. Owing to the dissecting action of the olive oil, curetting of necrosed tissue is not practised. In hot-air burns, cocaine and atropine sulphate should be added to the oil, and should be kept up for some days. After all this has been done a nebula remains; here thiosinamine lends its aid, although three months' constant use must elapse before we may expect any appreciable absorption. Three grains once daily for at least three months seem to give the best results.—*The Medical Age*, March 10, 1903.

An Epidemic of Acute Anterior Poliomyelitis.—Alice M. Woods reports twenty-five well-authenticated cases, and states that there are over thirty other children who are said to be subjects of the same epidemic. Most of the patients are under three years, the youngest only a few months, and the oldest ten and a half years. There is also one adult in the list. A large proportion were males. The paralysis was much more frequent in the lower limbs, the tibialis anticus muscle being particularly vulnerable. There was never more than one child affected in the same family. As to the etiology of this disease the consensus of opinion is that it is due to some infection; as yet there has been no conclusive evidence of a specific germ. If we consider the fact that this infection, often without warning, strikes down the young and vigorous and leaves them with more or less permanent injury, and that so far medical treatment has been of little use, it is evident that we must look forward to the science of preventive medicine as a means of escape from epidemics of this disease of childhood.—*Occidental Medical Times*, March, 1903.

SOME NEW VIEWS ON ASTHMA.

AFTER an experience of seven years in almost daily contact with a large number of asthmatics (including observation of many individuals for months and years at a time), Dr. M. Sihle of Odessa points out, in the *Wiener klinische Wochenschrift* for January 22, 1903, that in all asthmatics, both during the attacks and in the intervals, the inferior border of the liver, as determined by the "percussory transsonance" method of Henschen and Buch, is lowered, usually more than half way from the ribs to the navel, and in bad cases to within one or two fingers' breadths of the latter, and that the organ is sensitive to pressure. This uniform sensitiveness causes one to think, among possible conditions, of a condition of venous stasis. During three years Sihle measured the blood-pressure in all his asthmatics, between as well as during the the attacks, and found that, compared with measures for the normal by different observers of 95—110, 80—130, 80—120, his patients showed values mostly below 100 and even as low as 60; and, besides, a remarkable lability, one individual showed within five minutes values of 90, 70, 100, 85, and 75. On asking the meaning of this persistent low blood-pressure, he was told that naturally in the course of time the heart would weaken, etc.

While this easy-chair view may account for the low blood-pressure in chronic asthmatics, it does not account for it in those cases which have not yet become chronic, or in those in which the attacks occur at long intervals, *e. g.* six months or more. Is the low blood-pressure due to cardiac weakness or to deficient vasomotor tonus? Many cases in the intervals can make long marches and climb high stairs without noteworthy difficulty, which should exclude heart weakness. Further, Martius has shown that the congenitally weak heart muscle betrays itself by a broadening and strengthening of the heart impulse with a simultaneous decrease in the tension of the pulse, and by a diastolic splitting of the second sound, and by a lability expressed by a high pulse rate with still lower tension on slight exertion. While some asthmatics were found to have a condition of cardiac infraparity, the large majority showed no evidence that the heart was not up to the normal. Whence a persistent vasomotor subinnervation must be assumed. But as all authorities agree that during the attack bronchial spasm is present, how explain the anomaly of spasm here, atony there? Grossmann has shown that afferent stimulation of mixed nerves constantly produces increased blood-pressure and, in general, a simultaneous increase in the amount of work done by the heart, as measured by the intra-auricular pressure. In the case of certain nerves (particularly the superior laryngeal, the first and second branches of the trigeminus, and individual spots in the nose), however, the work of the heart is decreased. After section of the vagus in the neck, stimulation of peripheral nerve endings produces both bronchostenosis and general lowering of blood-pressure. In nasal asthma, then, trigeminus stimulation produces on the one side bronchostenosis while on the other it operates disturbingly on the circulation. The latter effect falls into two components, cardiac embarrassment and vasoconstriction. That in asthma the latter does not come to the surface, but that vasomotor depression rules the picture, is certainly due to simultaneous stimulation of the depressor nerve. The picture of asthma is thus the outcome of a complex stimulation of the various vagal functions, among the individual members of which there is a struggle for preëminence. Through a backworking from the embarrassed heart, the liver is congested. The so-called asthma "catarrh" is no true catarrh, but an anomaly of secretion, the outcome of nerve influence. We shall, however, have a hard time in displacing the term as, important though it is to estimate rightly its origin, in chronic asthmatics an ordinary bronchial catarrh frequently coexists. The specificity of the secretory disturbance lies in the suddenness of its appearance and disappearance, and in the character of the sputa. Sihle agrees with Hoffmann, Goluboff, and Fraenkel, that the characteristic of the sputum is rather the amount of the Charcot-Leyden crystals, spirals, and eosinophiles, than their mere presence. Any nerve may, perhaps, act as the asthmogenic centripetal path, but evidence is lacking that nerves other than the trigeminus, olfactory, and vagus, do so act, the so-called verminous and uterine asthmas being probably referable to the vagus. Probably the sympathetic does not act as an asthmogenic path, and at all events the vagus certainly occupies the first place. The efferent path is certainly the vagi.

Concerning the centers involved, it is not possible to speak with entire certainty, but from Kohnstamm's studies of the course of the vagus fibers and of their nuclei of termination and origin, it is probable that in all asthmas due to irritation in the bronchial and gastrointestinal mucous membranes, the uterus (?), and the genitalia (?), the solitary bundle represents the afferent path. As the same bundle contains sensory fibers from the trigeminus, in nasal asthma, too, it is probably the afferent path. Of the afferent path in asthma, due to olfactory irritation, we know nothing, and the same is true of the so-called neurasthenic and intoxication asthmas. Apart from the reflex asthmas, however, Sihle has seen many cases of cortical (or "psychic") origin. Also cases occur as a result of "taking cold" which are explicable on the ground of experimental studies of Kisskalt, who showed that the action of cold, even upon limited portions of the skin, induced a hyperæmia of the internal organs and mucous membranes. On the ground of the existence of transition forms and alternations between bronchial and cardiac asthma in the same patient, Sihle rejects cardiac asthma as a dis-

tinct form. In origin asthma is therefore peripherigenic, cerebrogenic, or hæmatogenic.

Regarding treatment, Sihle employs digitalis (15.0 of a 1.150 infusion) to combat the circulatory hypotonus, in combination with heroin (0.006) and iodide of potassium (0.50), every four to six hours, varying the proportions of the ingredients as one or another indication predominates. Where through long use the above remedies have lost their effect, belladonna should be used as in asthma it slows the heart and tones up the circulatory musculature. With pronounced heart weakness the theobromin preparations are invaluable. Arsenic (best as sodium cacodylate) is valuable for the feeble and anæmic, particularly children. The respiratory hyperæmia is to be combated by baths of gradually lowered temperature. Deep breathing exercises are to be used to increase the abnormally low vital capacity and to diminish the hyperæmia of the liver. All measures are to be fortified as far as possible by suggestion. No abstract can begin to convey a just idea of the scope and merits of this article.

DISEASE AND MARRIAGE.

The Vienna *Medicinische Blätter* for February 26, 1903, contains a discussion upon the above subject, partly in the nature of a review of the work of Dr. Henry Cazalis, *A propos des risques pathologiques du Mariage des hérédités morbides, et d'un examen médical avant le mariage*. The demand of Cazalis that individuals, or at least the man, be required, as a pre-requisite to marriage, to show a clean bill of health from such diseases as are liable to injure the other party to the marriage, or the offspring, is endorsed. The diseases particularly named are syphilis, tuberculosis, and alcoholism; also gonorrhœa. The consequences of the last for the woman are, as is known, much greater than for the man. But much more dangerous for the life of the individual, and for the whole race, is syphilis, which kills the offspring before or after birth, and floats as a Damocles' sword, in the form of general paralysis, over the head of the apparently cured patient. Alcoholism and its consequent mental disorders menace the offspring, the whole family, and the State. A medical examination should then be required, either by law or by custom. As, however, no sanguine hopes are to be entertained of such a drastic reform as a legal requirement of a medical examination, Cazalis limits himself to the following demands: (1) A pre-marital medical examination should be regarded as a moral duty, and the medical decision should be acquiesced in. (2) Hereditary and contagious diseases, especially those which menace the race, should be combated much more vigorously than hitherto. (3) The greatest diffusion of knowledge among all classes of the people should be favored, and, in particular, instruction should be given in the methods of preventing them, namely: (*a*) By giving every young man clear and brief information as to the dangers of venereal diseases, of alcoholism, and of tuberculosis, and (*b*) by giving similar instruction to every couple announcing their intention to marry, the instruction to embrace certain laws of physiology, of pathology, and of hygiene, which concern the health of the married, such as, the matter of conception and the health of the child. (4) This proposition is certainly the most original, the award of damages, by way of compensation, to the party who is infected by the other with a venereal or other severe disease in case the party at fault intentionally concealed his condition. In many cases it would, of course, be difficult to bring forward evidence of guilt, but such a definite pronouncement would nevertheless tend to lead one to guard himself against an eventual suit, by a medical examination. While there can be no doubt that the strict enforcement of these demands would be of the greatest consequence to the health and vigor of the race, nevertheless many adverse considerations are not to be lost sight of. New obstacles in the way of marriage will certainly operate to increase the number of "free unions," and, on the other side, will tend to diminish the birth rate to a considerable degree, which is an important consideration for a country such as France, where the decrease of the population has for a long time been a disquieting condition. Really, however, the "free unions" are for the race much less dangerous in consequence of their relative unfruitfulness, their object not being the production of children, whose advent is, indeed, an accident much feared. Cazalis also does not fear the decrease of the birth rate, as in most European States, while people limit themselves to two or three children, these two or three are strong and vigorous, so that, to a certain degree, lack of number is compensated by quality. For Cazalis, the most difficult feature in his demands lies rather in the fact that by interdiction of marriage many must be condemned to severe distress, but it must, he says, be remembered that, considering the circumstances, they are spared other pains which are perhaps much greater. In conclusion, Cazalis gives some indication as to the conditions under which marriage should or should not be permitted, in the hope of evoking enlightening discussion. In gonorrhœa the fact is rather simple; marriage is permissible if only a mucous discharge exists without gonococci and without leucocytes. Syphilitics can marry, provided they are at the time free from every symptom, that five years has elapsed since infection and a shorter or longer period of absolute immunity since the last manifestations, that they have not experienced the more malignant forms of syphilis, and that they have undergone a prolonged specific treatment. Regarding tuberculosis, marriage should be interdicted where the diagnosis is certain. Should tuberculosis appear after marriage, the latter should remain childless. If the tuberculosis is doubtful, the moral duty exists of abiding by the decision based upon medical examination. In cases of delusional insanity or alcoholism, from which the patient has apparently recovered, medical examination alone can determine whether marriage is permissible. The writer concludes by observing that, however much we may, from the medical standpoint, agree with Cazalis, the practical carrying out of his views would involve a revolution in our social ideas, as no law has ever undertaken to limit personal liberty in such a manner as is here proposed. But the suggestions of Cazalis deserve to receive consideration in the widest circles, and it is to be hoped that, at least partially, they may be carried out in the future.

FILIPINO STUDENTS FOR UNITED STATES.

The Filipino Federal Party, a native political organization, has just taken an important step toward the improvement of medical conditions in the Philippine Islands, by deciding to maintain in the United States, at its own expense, about thirty medical students annually. Students of law, pedagogy, engineering, agriculture, and veterinary science will also be sent out, the total number of students to be maintained to amount to about 250. The medical student appointees will be selected as a result of competitive examination from among the natives; and those coming from poor families, other things being equal, are to be given the preference. A number of universities and colleges in the United States have offered gratuitous instruction to a limited number of Filipino students, and the Federal Party will allow the latter the sum of $425 per man for annual expenses during a period of two years. The plan proposed is to send fifty students to the United States during the coming year, of which six will study medicine; 100 are to go the second year, of which twelve are to be medical students; in the third year all vacancies in those originally sent out are to be filled, and fifty additional students, including six students of medicine, sent out. Thereafter the total number of students to be maintained is to be 250. In addition to these students to be supported in the United States, it is proposed to send some specially prepared students to Europe for further study. This action of the Federal Party is to be highly commended, and shows that the natives are at least awakening to the urgent medical needs of their islands. It is true that the proposed instruction of six medical students yearly will do but little toward satisfying the medical necessities of the Philippines, but they will form a nucleus among the Filipinos standing for a higher medical education among the native physicians than has heretofore been attained. This is most important, for American physicians can never come in touch with the great mass of the people of the Philippines by reason of difference of race, language, and customs, and the Filipinos must look for their medical attention to physicians drawn from their own ranks. This patriotic action of the Federal Party is much to be commended, especially as such high purpose by a political organization was scarcely to be expected. It now remains for the medical colleges of the United States to meet this action half way, and facilitate, as far as possible, a humanitarian movement which should prove of great advantage to the millions for whose health and welfare this country is now responsible.

Etiology of Sleeping Sickness.

The British Royal Society some time ago dispatched a commission to investigate into the outbreak of sleeping sickness in Uganda. The secretary of the society has recently received a communication on the matter from Dr. Aldo Castellani, one of the members of the commission. The report of Dr. Castellani is given in the *British Medical Journal*, March 14. A large portion of this report is taken up by a consideration of the researches of, and the results reached by, former investigators into the origin of sleeping sickness. The author, however, does not agree with the findings of any of these, but states that he has found an organism which he thinks he has good reason to consider to be the cause of sleeping sickness. He declares that he has grown it with absolute certainty—and always pure—from eight out of ten necropsies from the cerebrospinal fluid and blood of the heart taken with aseptic precautions. In life he found it only once in the blood, but has grown it in two cases out of three from the cerebrospinal fluid removed by lumbar puncture. The germ may be considered as a distinct variety of the streptococcus group. The microscopic appearance is very variable, depending on the different media on which the germ has been cultivated and on the different terms of growth, etc., all transitions from long chains to typical diplococci being seen. The form and size of individuals is also, under certain limits, variable. Frequently about the chains and the diplococci forms well-defined mucoid capsules are seen, and in hang-drop preparations the short chains and the diplococci-forms show a well-marked Brownian movement. In old cultures involution forms are produced, frequently single members present larger dimensions, and sometimes they present the form of a club.

Testing in various ways has made Dr. Castellani come to the conclusion that the germ which he isolated must be regarded as a new variety of streptococcus. Among other reasons for holding this opinion he gives the following: That the cultivation on gelatin is sufficient to differentiate it from the streptococcus lanceolatus, as the latter does not grow at all, or only very badly on that medium. From the streptococcus pyogenes it is differentiated by its much more vigorous growth on all media, and especially on agar, by the tendency of its colonies to coalesce, and by the non-coagulation of milk. As regards the diplo-streptococcus of the Portuguese, the author does not think that any confusion can arise. The Portuguese state that the culture of their germ generally failed every time on the usual media like agar, gelatin-agar, etc., and with gelatin they never succeeded in obtaining cultures. The streptococcus described by Dr. Castellani grows very well on gelatin and on all the other usual media. This character differentiates the organism also from the streptococcus intracellularis, which does not grow at all, or very badly on gelatin, and also, according to some authors, on cow serum.

The experiments have not as yet been complete nor numerous enough to prove absolutely that the organism found by Dr. Castellani is the cause of sleeping sickness, but the investigations so far have encouraged a strong belief in such a result.

Infant Life Insurance.

The death under suspicious circumstances of a number of children recently in a neighboring city has helped to direct attention to the dangers and the temptations surrounding life insurance in the case of young children. This practice is not at all uncommon among the poorer classes, and is intended to afford a means of providing for the payment of necessary burial expenses. That such a state of affairs may become a matter of serious importance is shown further by the observations of a French physician, M. Budin (*Lancet*, March 29, 1903, p. 843), who calls attention to the excessively high mortality among infants in certain departments in the north of France, where he found that a regular premium exists on infant mortality. Certain Belgian insurance companies for a small sum insure children in infancy or even before birth, the parents receiving the money, nominally for burial expenses, in case of death. As among those, however, who take out such policies these expenses are borne by the State,

ne proceeds represent pure gain to the beneficiaries. .n infant may thus be insured in several different ɔmpanies and also by a third person without the nowledge of the parents. The case is cited of a urse who secured the insurance money on the lives f seven out of eight children that died under her are, some of the infants being insured in several ɔmpanies, without the cognizance of the parents. o far as can be ascertained, there is no legal method y which such insurance companies can be prevented rom carrying on their business on French territory.

rofessor E. A. Wright on Dr. Macfadyen's New Anti-typhoid Serum.

Dr. E. A. Wright, the discoverer of a method of ıoculation against typhoid fever which has been ven a lengthy trial among soldiers of the British rmy in India and South Africa, with somewhat egative results, writes a critical article in the *ritish Medical Journal*, April 4, on Dr. Macfadyen's ıti-typhoid serum. Dr. Wright lays down these ropositions, which he says can only be regarded as ɛiomatic: (1) The vaccine material must be derived om a culture of the bacillus typhosus. (2) Owing) the risk which would attach to the employment of ving cultures the vaccine material must consist ther of a sterilized typhoid culture or of a con-ituent isolated from such a culture. (3) The ıccine material, however constituted, must be free ɔm contaminating microorganisms. Judging from s own experience, Dr. Wright is of the opinion that r. Macfadyen's recorded experiments seem to show ıat the trituration of the typhoid bacteria at the ımperature of liquid air, which constitutes the chnical innovation introduced by the latter, rings about only what is effected spontaneously the organism when the typhoid bacillus is oculated into the system. Dr. Wright does ɔt think that in view of the difficulty which has ɛen experienced in effecting the sterilization of ıbercle cultures by trituration, that such a method sufficiently valuable to repay the labor of prepara-ɔn. So far as the standardization of the vaccine concerned, the author thinks that Dr. Macfadyen's ethod is more complicated than his own. Dr. acfadyen, according to the writer, regards his ıccine material as entirely *sui generis* and believes ıat he has discovered the elaboration of a novel ement, to wit, of a typhoid antitoxin in the blood his inoculated animals. Dr. Wright, however, ates that his view of the matter is that there is ɔthing novel in the vaccine material devised by r. Macfadyen, except that it was prepared with quid air, and that, further, we have as yet no ɛason to conclude that any novel immunizing ement has been developed by the inoculation of ıis vaccine material. Lastly, with regard to the uestion of the serumtherapy of typhoid fever, the uthor contends that even if it be established—hich is very doubtful—that Dr. Macfadyen has evised a novel vaccine material, which induces ıe elaboration of a novel antitoxic element in ıe inoculated organism, the problem of serum-ıerapy is not necessarily brought any nearer) a practical solution. There is absolutely—he ɛclares—no outlook for the successful practical ɛploitation of an antitoxic serum against any ɛsease, unless, as obtains in the case of antidiph-ıeria serum, the quantity of antitoxin contained in ıe few cubic centimeters of foreign blood which can ɛ inoculated into the patient is sufficiently con-derable to neutralize at least a substantial fraction the bacterial toxin generated in his system. If ıerefore, Dr Macfadyen's vaccine material does not fulfil this condition, his discovery will have helped but little toward providing a successful anti-typhoid serum.

Observations as to Taking Temperature.

Drs. F. W. Burton Fanning and S. Gurney Champion of Norwich, England, have been making investigations, recently recorded in the *Lancet*, March 28, with regard to (1) the relationship of the relative readings of the thermometer when placed in the mouth, the rectum, the urine, the axilla, or the groin; and (2) the effects on the temperature of exercise in health, in tuberculosis, and in some diseases. They found that the time usually allowed for the thermometer to remain in the mouth is too short to give an accurate reading. On occasions thirty minutes may be required to obtain correct results. In these instances the thermometer used may not be in fault, but it takes that length of time for the buccal cavity to regain its normal heat, after it has been cooled down by a cold external atmosphere by breathing with the mouth open. Exercise is especially liable to cause errors when the temperature is taken soon after such exertion, as it entails more rapid respiration, usually with the mouth open, the result being that the buccal cavity becomes cooled below the temperature of the rest of the body. Rectal observation shows that exercise produces a rise in temperature, but this rise does not last for longer than half an hour from the cessation of activity. Cooling the buccal cavity by means of ice has much the same effect, and an ice-bag applied to the side of the face for fifteen minutes reduced the temperature on that side of the oral cavity by 4.4°, while the mouth took one hour to recover its normal temperature after the ice-bag had been taken away. The authors decided that the rectal temperature is the surest guide as to the condition of affairs, for the reason that the maximum reading in the rectum is obtained in from one to five minutes. The rectal temperature is an index more to be relied upon than are the inguinal, axillary, and urinary. The passage of five ounces of urine over the bulb of the thermometer is a fairly correct method of taking temperature, but not to be altogether depended on in all cases, as the authors found that unexplainable discrepancies occurred once in every twenty observations. The time needed to obtain a correct reading in the axillary and inguinal regions is generally from 15 to 60 minutes. As to the effect of exercise on temperature, the writers state that it has been, as a rule, underestimated. A slight amount of movement only will cause the mercury to rise to an appreciable extent, and further exertion has produced rise of as much as three and one-half degrees. The authors made their observations under these conditions, which they claim to be essential to good results: (1) Absolute rest. In this condition the temperature is actually depressed. (2) Standing without taking active exercise, which tends to raise the temperature slightly. (3) Active exercise, which distinctly raises the temperature. The manner in which the above conditions were observed by the authors was as follows: Slight muscular efforts were tested thus; on walking in the morning the temperature of a healthy individual was taken; he then got out of bed and stood up, but did not walk, and the readings were taken off. In one the temperature was 98.2° in bed; after standing up for half an hour the mercury had risen to 99°. Experimenting on eight healthy subjects the average rise was found to be 0.3°. The tests applied in investigating the effects of active exercise were as

follows: In mild weather a moderately hard bicycle ride of half an hour was taken, which caused slight perspiration. Before starting, the temperature was —rectal 98.8° and buccal 98.3°. At the end of the ride the readings were—rectal 99.5° and buccal 99°.

Dietectic Factors in Health-resort Treatment.

At a meeting of the British Balneological and Climatological Society, held on March 18, Dr. F. A. Mouillot introduced a discussion on the subject and said (1) that a considerable portion of diseases treated at Spas was due to faulty metabolism, and that gout, obesity and glycosuria were the chief of these diseases and were closely connected. (2) That gout, in its widest sense, was due to the development of certain poisons in the process of digestion, and that these poisons were best limited by a simple meat dietary. (3) That it was irrational to consider food or drugs solely from the point of view of their acidity or supposed solvent power on uric acid. (4) That if a patient was properly dieted at home no marked change ought to be made in the diet at the Spa, more particularly should the quantity of food not be restricted whilst undergoing a treatment which made a great strain on the activity of the system. (5) That the education which the patient received as to the regular consumption of non-alcoholic fluid apart from meals was a useful one. (6) That an attempt to treat obesity by withholding fluids was to be condemned as leading to the production of serious diseases and ill-health, and that though it was right to diminish the quantity of fluid taken at meals it was wrong not to make up for that limitation by giving water apart from meals, and (7) that alcohol should be taken in very limited qualities, if at all, and that in the case of gout, whiskey, still moselle and still cider seemed least harmful. Dr. Harry Campbell made a good point when he said that for the long period which elapsed before man learnt to cook his food and to till the soil his supplies of starch were limited and subjected to such thorough mastication that very small quantities of crude starch passed into the stomach; whereas in this stage of abundant starch and imperfect mastication the stomach and intestines were flooded with undigested starch, which give rise to many evils. Dr. Léon Blanc of Aix-les-Bains, speaking specially of the diet in gouty cases, said that the diet regulations were not very strict in France, because the ordinary food was comparatively light. He gave mixed diet, including meat, only twice a day, and preferably beef and mutton, which must be boiled if possible. Game, venison, pork, and preserved meats were forbidden. All vegetables were good, and fresh fruits, especially acid fruits, were taken between meals, but alcohol was strictly interdicted. Dr. Schott of Nauheim said that every case must be provided for according to its own individual peculiarity. He advocated a mixed diet in heart cases, and small and frequent meals, generally at intervals of three hours, and of high nutritive value. Alcohol should be taken in a state of high dilution.

The Bill against Drug Substitution.

As we go to press, word reaches us that the Bostwick-Dowling bill relating to drug substitution has passed the Senate by a commendable majority, and is now in the hands of the Governor for his signature. This Bill changes Section 401 of the Penal Code, so as to read as follows:

"Any person, who, in putting up any drug, medicine or food or preparation used in medical practice, or making up any prescription or filling any order for, or selling any such drug, medicine, food, or preparation omits to label the same, or puts any untrue label, stamp or other designation of contents upon any box, bottle, or other package containing a drug, medicine, food, or preparation used in medical practice, or substitutes or dispenses a different article for or in lieu of any article prescribed, ordered, required or demanded, or puts up a greater or less quantity of any ingredient specified in any such prescription, order, requirement or demand, than that prescribed, ordered, required or demanded, or otherwise deviates from the terms of the prescription, order, requirement or demand, is guilty of a misdemeanor; provided, however, that, except in the case of physicians' prescriptions, nothing herein contained shall be deemed or construed to prevent or impair or in any manner affect the right of an apothecary, druggist, pharmacist, or other person to recommend the purchase of an article other than that ordered, required or demanded, but of a similar nature, or to sell such other article in place or in lieu of an article ordered, required or demanded, with the knowledge and consent of the purchaser. Upon a second conviction of a violation of this section the offender must be sentenced to imprisonment for a term of not less than ten days nor more than one year, and to the payment of a fine of not less than ten dollars nor more than five hundred dollars. The third conviction of a violation of any of the provisions of this section, in addition to rendering the offender liable to the penalty prescribed by law for a misdemeanor, shall forfeit any right which he may possess under the law of this State at the time of such conviction, to engage as proprietor, agent, employee or otherwise, in the business of an apothecary, pharmacist or druggist, or to compound, prepare or dispense prescriptions or orders for drugs, medicines or foods or preparations used in medical practice; and the offender shall be by reason of such conviction disqualified from engaging in any such business as proprietor, agent, employee or otherwise, or compounding, preparing or dispensing medical prescriptions or orders for drugs, medicines, or foods or preparations used in medical practice."

To this bill we give our unqualified endorsement, and in view of the gravity of the situation, we wonder why the law was not made thus definite and exact long ago.

The requirements permitting an individual to practice medicine in this State are most rigid There is every reason why the conditions surrounding the filling of a physician's prescription should be equally so.

We cannot conceive that the Governor will do otherwise than promptly sign this commendable bill. Other States should pattern after New York and enact similar legislation.

The Infallibility of Galen.—In the year 1559, John Geynes, M.D., a graduate in medicine of the University of Oxford, was cited before the College of Physicians for impugning the infallibility of Galen. On his acknowledgment of error, and humble recantation, signed with his own hand, he was received into the college.—"The Roll of the Royal College of Physicians of London."

News of the Week.

Professor Mikulicz's Visit to America.—J. Mikulicz, the eminent Professor of Surgery of Breslau University, is on a visit to this country in response to an invitation to read a paper before the American Surgical Association at its coming meeting in Washington, D. C. While in New York during the past week he was the guest of Dr. F. Kammerer, who tendered him several private dinners, and also a reception attended by a number of the leading surgeons of this and neighboring cities. He has also been entertained at luncheon by Dr. Robert Abbe, and at dinner by Prof. Robert F. Weir. By invitation of Prof. Wm. M. Polk, dean of the faculty of Cornell Medical College, Professor Mikulicz held an operative clinic at Bellevue Hospital before a large and representative audience of medical men anxious to witness the dexterity and skill of the famous German operator. The professor, while visiting Philadelphia, was the guest of Prof. W. W. Keen. He will also respond to an invitation to visit the Johns Hopkins Hospital at Baltimore, and will give a surgical clinic for Dr. John B. Murphy at Chicago.

Bergen County (N. J.) Medical Society.—At the annual meeting of the Bergen County Medical Society, held at Hackensack on April 14, Dr. W. Gill Wylie read a paper on "Mental Overstrain in Young Girls," in which stress was laid on the high grade of school requirements in New Jersey.

The Twenty-eighth Annual Meeting of the American Academy of Medicine will be held in the large banquet hall of the "Arlington," Washington, D. C., on Monday and Tuesday, May 11 and 12, 1903.

The American Proctologic Society.—The fifth annual meeting will be held in New Orleans, La., on May 5 and 6, 1903. The first session will begin at 2 P.M. on Tuesday, May 5. The place of meeting will be in the parlor of the New St. Charles Hotel.

Louisiana Quarantine.—The Louisiana State Board of Health has refused to agree to the proposition of Dr. Lindsay of Havana that it make its quarantine regulations conform with those of the Public Health and Marine Hospital service, that it use the Marine Hospital inspectors instead of its own, and that coastwise vessels be relieved of the necessity of inspection upon entering New Orleans. The Louisiana Board will, as heretofore, maintain its own inspectors at the gulf ports where there is considered to be any danger of importation of yellow fever or other disease.

State Boards of Medical Examiners.—In a neighboring state attempts are being made to alter the medical practice act by abolishing the existing three State Boards of Medical Examiners and substituting therefor a single board to be composed of representatives of the various legally recognized schools of medical practice. Similar legislation was attempted in New York State, but was fought, tooth and nail, by the representatives of "pathies" and "isms" in medicine, with the result that a compromise measure, in the form practically of the present act, or none, had to be adopted. Twelve years of experience have made some difference in the ideas of those who were opposed to our views on this question, and the time is doubtless drawing near when the original spirit of distrust will have given way to a feeling of confidence. When that time arrives the initial plan of the State society for a single mixed board of examiners will be carried into effect and none will be stronger advocates of the departure than those who were its erstwhile opponents. In the meantime we must be patient and be content with what we have.

The Sale of Liquor in Russia.—The experience of the Russian government in attempting to regulate the sale of liquor in certain districts has proved a failure, if the statistics compiled by Professor Cholsky are reliable. These figures show an increase in drunkenness (not only generally, but in the homes of the people) and an increase in the per capita consumption of alcoholics. The temperament of a people is always a factor in such a test. Similar restrictions applied to citizens of other countries might prove highly beneficial, and any number of instances can be cited in which regulations such as were supposedly enforced in Russia, applied elsewhere, have lessened drunkenness and reduced the sum total of liquor consumed. Again, unpopular laws are not always enforceable.

Bill for Educational Commission.—On April 21 Assemblyman Landon, Chairman of the Committee on Public Education, introduced a bill into the New York State Assembly to carry out the suggestions of Governor Odell with reference to an investigation of the educational controversy in the State. It authorizes the Governor to appoint within thirty days a commission of five persons who are to report to the Legislature on or before February 1, 1904.

Last of the Child Labor Bills.—On April 21 the New York State Senate passed the last of the child labor bills framed by the Child Labor Committee, of which Robert Hunter, head worker of the New York University Settlement, is Chairman. It amends the Penal Code so as to provide penalties for false statements in connection with the employment of children.

Passage of Street Cleaning Bill.—On April 21 the Senate passed Senator Plunkitt's bill amending the New York City Charter with reference to the Street Cleaning Department. It represents the views of the city administration, and increases salaries, adds to the department, and gives it authority over the sprinkling and sanding of streets.

Trained Nurses' Meeting at Albany.—The New York State Nurses' Association met in Albany on April 21. It discussed the bill providing a board to examine and license trained nurses in the State, which has passed both branches of the Legislature. At the close of the afternoon session the delegates called on Governor Odell and requested him to sign the bill. He said that the measure had not reached him, but that when it did he would give it his earnest consideration.

Lunacy Bill Vetoed.—Governor Odell has vetoed the Ramsperger bill providing for a treasurer and a purchasing agent for the State hospitals.

Passage of a Bill for a Commission of Inquiry to Investigate the Condition of the Adult Blind of New York State.—The bill creating a commission to investigate the condition of the adult blind in New York State passed the Assembly on April 21 by a vote of 79 to 43. Its main purpose is to provide methods whereby the adult blind of the State may be taught trades.

Typhoid Fever at Stanford University.—Typhoid fever is rife at Stanford University, California. It is reported that twenty additional cases have broken out, bringing up the total number since the first appearance of the epidemic to almost one hundred cases. The mortality up to the present has been very slight. As to the proposed closing of the university, President Jordan says that while conditions are as they are, and while the

physicians are of the opinion that the trouble is almost checked, no action in this direction will be taken.

Man Coughed up Worm.—A man named Fay, who had served in the Philippines, is reported to have coughed up a worm a few days ago five inches in length. Dr. Price, the surgeon at the Brooklyn Navy Yard—where Fay was working—and Dr. Sprattling, his assistant, thought it was an angle worm, but were not positive as to its species. Surgeon Sprattling, however, who was stationed in the Philippines for some time, recollected that men had reported to him there that they had coughed up worms. The theory was that in drinking dirty cistern water, the man swallowed the eggs of these worms, which afterward hatched in the stomach.

Ventilation of New York Subway.—There will be some difficulty in providing an efficient system of ventilation for New York's subway. Although the stations will be near the surface of the streets, it is apprehended by bacteriologists that unless means are taken to provide artificial ventilation that there will be fear of a vitiation of the air. Probably a system of power fans, or something equivalent to fans, will be used for ventilating purposes.

American Academy of Medicine.—The twenty-eighth annual session of the American Academy of Medicine will be held at the "Arlington," Washington, D. C., on Monday and Tuesday, May 11 and 12, 1903. A very interesting program is promised.

American Gynecological Society.—The twenty-eighth annual meeting of the American Gynecological Society will be held in Washington, D. C., on May 12, 13, and 14, 1903, in Lecture Hall No. II, Medical Department Columbian University, No. 1325 H Street.

The National Association of United States Pension Examining Surgeons will be held in Washington, D. C., on May 13 and 14, 1903. The officials of the Pension Bureau have kindly volunteered to do all in their power to make the stay of the members in Washington both pleasant and profitable. Every facility will be afforded them to inspect the workings and methods of the Bureau. Commissioner of Pensions Ware has consented to deliver an address of welcome, and Medical Referee Houston will read a paper before the association.

Death of an Anti-vaccinationist.—Mr. Stevens, the late secretary of the Anti-vaccination League of Minneapolis, died in that city on April 15 of malignant smallpox. Mr. Stevens had been in the custom of denouncing vaccination on every possible occasion, as a barbarous practice, entirely without efficacy in either preventing or staying the progress of smallpox.

Physician Takes Poison by Mistake.—Dr. Pope of 926 Mark Avenue, Brooklyn, took by mistake, on April 14, a large dose of nux vomica. He was taken to the Cumberland Street Hospital, and it is thought that he will recover.

Objection to Hospital for Consumptives in Orange County.—Mr. E. H. Harriman is responsible for the introduction of a bill in the State Assembly by Senator Godsell to prevent the building of a proposed hospital camp for consumptives in Orange County. Land for the camp had been offered by Charles F. Fowler of Central Valley. Unfortunately for the success of the project, Mr. Harriman owns a considerable tract of land in the vicinity of the suggested camp site, and has brought his influence to bear to defeat the plan. The bill brought in by Mr. Godsell amends the public health law by adding to it the following new section: "A hospital camp or other establishment for the treatment of patients suffering from the disease known as pulmonary tuberculosis shall not be established in any town by any person, association, corporation, or municipality unless the Board of Supervisors of the County and the Town Board of the town shall each adopt a resolution authorizing the establishment thereof, and describing the limits of the locality in which the same may be established.

The Late Prof. T. Gaillard Thomas.—At the meeting of the New York Obstetrical Society, held April 14, 1903, the following resolution upon the death of Dr. T. Gaillard Thomas, presented by the committee appointed at the last monthly meeting, was adopted:

"In paying its tribute of respect to the memory of T. Gaillard Thomas, the New York Obstetrical Society takes pride in the thought that he was one of the founders, several times its president, and for many years one of its most active and honored members. It is a pleasure to recall the various incidents and upward steps in his career, how he came to New York a poor young practitioner without friends, and with hardly an acquaintance, and how, by sheer ability, he soon made himself felt, and left the impress of his personality wherever it was his destiny to labor.

"In his day he was a leading authority on all gynecological and obstetrical subjects. As an operator, he was *facile princeps*. He was not only theoretically the master, but his technique was unexcelled.

"Who, that listened to his lectures, was not impressed with the forcefulness of his style, and the breadth of his erudition.

"He has passed from among us, having reached the forefront of professional eminence, satisfied and content, and rich in the rewards and honors of his career.

"It is proposed that these words be entered upon our minutes, and a copy be sent to the family and the medical journals.

CLEMENT CLEVELAND,
J. E. JANVRIN,
GEO. TUCKER HARRISON."

Resolution of the Medical Board of the General Memorial Hospital:

"*Resolved*, That by the death of Dr. T. Gaillard Thomas we have lost an eminent and highly esteemed member of the consulting staff, who had been connected with the hospital since its foundation. He has gone to his reward, crowned with years and honors, wearing both with grace and dignity.

"*Resolved*, That a copy of this resolution be sent to the family of the late Dr. Thomas, and that it be published in the medical press."

Hospital in Philippine Mountains.—It has been arranged to erect a large modern hospital and convalescent home in the mountains of the Philippines near Mariveles, at an elevation of about 3,000 feet. Lieut. J. A. Woodruff of the engineer corps and Capt. C. C. McCullough, assistant-surgeon, have been detailed to select a suitable site, and it is hoped to begin the work of construction as soon as this has been done. It is intended to provide a general station where officers and men suffering from the effects of tropical service may be sent to recuperate.

Hospital for Sailors at Home.—A sailors' hospital has been established at Cape Nome, Alaska, in con-

nection with the marine hospital service, and the hospital at Dutch Harbor will be abolished. The *New York Tribune* states that the establishment of a relief station at the port of St Michael for the river men is also contemplated.

Scientific Temperance in Schools.—Mrs. Mary H. Hunt of Boston, Mass., delivered an address at the International Anti-alcohol Congress recently held in Bremen, on the significance of scientific temperance instruction in public schools as a preventive of alcoholism.

To Kill Flies by Typhus Germs.—"Rattlesnake Fry Pond, up Eustis way," says the *New York Tribune*, "holds the record in Bemis County, Me., for black flies. They rise in clouds over the pond, and almost eat up sportsmen who venture up there. Now comes Prof. Frederick Stickmore of Chicago, who says that he can not only rid the pond of its pests, but also can kill all the black flies in Maine. He has just arrived at Bemis, and is preparing for his work of extermination with a typhus bacillus that he says is death to all flies. This disease, he says, will kill a black fly thirty minutes after being exposed to it. The stickmore typhus is contagious, and would, it is said, soon exterminate them. Maine guides are trying to secure a supply for private use."

Increase of the Medical Corps of the Navy.—The Fifty-seventh Congress in its last session provided for an increase of 150 members in the Medical Corps of the Navy, twenty-five of which are to be appointed each calendar year for six years. The number of vacancies in this corps occurring from retirements, resignations, and casualties average about ten a year, which added to the twenty-five created by new legislation, makes thirty-five appointments open to young medical men yearly. These appointments are to be made in the grade of assistant surgeon, and are within reach of any well-qualified physician between the ages of twenty-one and thirty years, who is a citizen of the United States. Examinations to determine the fitness of candidates for appointments are held in Washington D. C., and at Mare Island, Cal., and the boards of examiners are in continuous session throughout the year. It is only necessary for any physician of the required age and citizenship desiring to enter the Medical Corps of the Navy to apply to the Secretary of the Navy for permission to be examined to insure being given an opportunity.

The examinations to determine the fitness of candidates for these appointments are conducted in the following order: (1) physical; (2) professional; (3) collateral. The physical examination is thorough, and the candidate is required to certify, on oath, that he is free from all mental, physical, and constitutional defects. If found to be physically qualified, his examination is continued as follows: Letter to the board describing in detail his general and professional education. The professional examination includes anatomy and physiology, surgery medicine, pathology and microscopy, obstetrics and medical jusisprudence, materia medica and physiological action of drugs, chemistry and physics, hygiene and quarantine, general aptitude, literary and scientific branches. Required aggregate of marks 750 out of a possible 1,000.

In addition the candidate must satisfy the examiners in the following subjects: Bandaging, tourniquets, four operations on cadaver, clinical cases, urinalysis, practical microscopy and recognition of five mounted specimens, recognition of surgical instruments. The oral examination follows the written work in each branch, and the required percentage is made up from the combined results of the written and oral examinations. The percentages given are not absolute, however as losses in some branches may be made good in others, provided the standard is reached in the cardinal subjects of anatomy, physiology, medicine, and surgery. The collateral examination is to show that the candidate has received a good general education. The following is the pay table of the Medical Corps of the Navy: Assistant surgeons, rank of lieutenant (junior grade), at sea, $1,650; on shore, $1,402.50. Allowances, per annum, in every case only when quarters are not furnished by government, $228. Passed assistant surgeons, rank of lieutenant, at sea, $1,980; on shore, $1,683. Allowances, $432. After five years in the service, at sea, $2,340; on shore, $1,836. Allowances, $432. After ten years in the service: at sea, $2,340; on shore, $1,989. Allowances, $432. Surgeons, rank of lieutenant-commander, after ten years in the service, at sea, $3,250; on shore, $2,762.50. Allowances, $576. After fifteen years in the service: at sea, $3,500; on shore, $2,975. Allowances, $576. Medical inspectors, rank of commander, after fifteen years in the service: at sea, $4,000; on shore, $3,400. Allowances, $576. Medical directors, rank of captain, after fifteen years in the service: at sea, $4,500; on shore, $3,825. Allowances, $720. Surgeon-general, rank of rear admiral, at sea, $5,500; on shore, $5,500. Allowances, $720. The navy medical service, as a career for a young man, offers many advantages. The pay is sufficient, promotion is fairly rapid, and the professional opportunities provided are good. The medical man in the navy also sees the world under very favorable auspices. In short, it may be said that the lot of a naval medical officer is far better than that of the majority of civil practitioners.

Salt Cure for Cancer.—It is reported from Simla, India, that Captain Rost of the British Army Medical Service has announced that he has discovered what he believes to be a cure for cancer. Captain Rost has been investigating the matter for three years at the hospital Rangoon, Burmah, and states that he has found in both carcinomata and sarcomata cancers distinct germs of saccharomycetes, which can only develop when the natural chlorine in the tissues falls below the normal quantity. Captain Rost proceeded with treatment suggested by this fact, reinforcing the chlorine of the body by special diet, enabling large quantities of common salt to be absorbed. Eight patients have been made the subjects of experiment. One is said to be completely cured and the condition of the others improved. The experiments are being continued.

Obituary Notes.—Dr. Mathew Gardner, Chief surgeon of the Southern Pacific Company, died in the railroad hospital at San Francisco on April 18, as the result of an operation for appendicitis.

Dr. Frank B. Wiliams died on April 19 at 533 Bedford avenue, Brooklyn, aged thirty-nine years. He was a graduate of the College of Physicians and Surgeons.

Dr. James Bonaparte Greeley, great-grandson of Dr. Matthew Thornton, signer of the Declaration of Independence, died at Thornton's Ferry, N. H., on April 19, of heart disease, aged seventy-three years. His paternal great-grandfather fought at Lexington and Bunker Hill, in the latter of which he was wounded.

Dr. F. W. Anderson of Salt Lake, Utah, who attended President Brigham Young in his last illness, died in that city on April 20, aged eighty-one years. He was the oldest practising physician in Utah.

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent.)

HOSPITAL SUNDAY—HONORARY DEGREES—PARLIAMENTARY ACTIONS AT LAW—ACROMEGALY—BILHARZIA—GANGRENOUS BOWEL—HÆMOGLOBINURIA AND TRAUMATISM—MOLLUSCUM FIBROSUM IN CHILDREN—TUBE RAILWAY—NOTIFICATION—CHANGE OF A DISPENSARY—OBITUARY.

London, April 3, 1903.

Hospital Sunday Fund is fixed for June 7, and the King and Queen have intimated their intention to attend the service at St. Paul's on the occasion. The London University will confer the degree of Doctor of Laws on the Prince of Wales, Doctor of Music on the Princess, and Doctor of Science on Lord Lister and Lord Kelvin on June 24. Parliament has only lightly touched medical matters. The sale of poisons, the medical services of the navy, army and volunteers, the Royal Army College, vaccination, physical tests for recruits, cremation, adulteration of butter—all these at home have been the subject of questions or representations, but I cannot say that the answers or statements are of much interest or importance.

After a hearing, extending over three days in the High Court, a jury has found damages (£250) against a district Council for alleged negligence in its provision for smallpox. On the notification of a case the Council fitted up a disused stable as a temporary isolation hospital and removed the patient to it. A child living some distance off died of the disease and her parents took it. They brought this action. No evidence was offered as to whether the child went near the stable. Contradictory evidence was given as to the burying of all refuse with quicklime. The judge put to the jury: (1) Was the hospital a nuisance occasioning damage to plaintiffs? (2) Was there want of proper care and skill by the authorities or their servants? He said every one would sympathize with a health authority on an outbreak like this, but he hoped it would be a warning to all public bodies to prepare in advance for such outbreaks. Expert medical evidence testified that the hospital was properly fitted up for the purpose and was at a reasonable distance from houses. The plaintiff worked on the land near the hospital and had not been revaccinated. Query—was not he as negligent as the Council?

An action was commenced by a nurse against Professor Byers for breach of promise. But when it came to be heard the nurse would not appear in support of her charge, which the professor had all along denied. The judge remarked that he presumed she had no cause of action and entered judgment against her with costs. But will these costs be recoverable? In these cases of attempted blackmail that is seldom the case. It is one of the dangers to which medical men are liable. It seems hard that when a false charge is brought of this kind the accuser cannot easily be brought to book for attempted blackmailing.

Dr. H. A. Lediard related to the Clinical Society on Friday a case of acromegaly with goiter in a woman of forty-three years. The patient was shown, and her feeble muscular power demonstrated. The features and expression were characteristic. In June, 1902, the left lobe of a bilateral goiter of several years' growth was removed on account of stridor and dyspnœa, due to pressure. Radiographs and microscopic slides were shown. There was no general increase in size, but the features were so enlarged she could not be recognized by her relatives. Since operation she has gained some pounds in weight, but there was no change of pulse or temperature.

Dr. Andrew Duncan read notes of a case of bilharzia contracted in South Africa. The urine contained numerous ova, as well as blood, mucus and a little albumen. Three papillomata round the anus on removal were stuffed with the ova. Methylene-blue had been given, but so far treatment was without effect. It was now proposed to try male fern. Dr. Manson remarked that condylomata round the anus were uncommon, though internal growths were frequent in the rectum. It was remarked by others that the Boers in some districts knew that drinking from some streams produced the disease. Treatment was generally considered of little avail, and any suggestions would be welcome. Ova discharged from the bladder usually had a terminal spine, but from the rectum a lateral spine, though this was not invariably so. Some thought the distinction represented two species of the parasite. Mr. Makins, C.B., then read notes of two cases illustrating the employment of imagination and stitching over gangrenous patches of intestine in the treatment of strangulated hernia. The first was in an old man, eighty-seven; the second, a male infant of nine weeks. The man had been subject of hernia for seventeen years. On strangulation an operation revealed a sac containing red, offensive fluid, six inches of small intestine with a gangrenous patch perforated in the center, and a single free apple pip. Thus the case was rather one of perforation. But the gangrenous patch was inverted by Lembert's sutures, the gut cleansed, the neck of the sac removed, and the bowel returned. The wound was plugged, granulated well and the man left hospital on the forty-eighth day. The infant's case was an ordinary gangrenous partial enterocele, and invagination successful. Some other cases were mentioned by the surgeons present. Mr. Bowlby said he had for some years adopted the plan of bringing together the peritoneum over gangrenous bowel rather than the extensive resection which some surgeons frequently resorted to. The President, Mr. Howard Marsh, hoped that free resection would be less practised. He had often adopted the practice advocated by Mr. Makins, especially in femoral hernia.

Drs. C. W. Ensor and J. O. W. Barratt read a paper at the Medico-Chirurgical Society on "Paroxysmal Hæmoglobinuria of Traumatic Origin." The patient was a lunatic, who for some years had the habit of beating his forehead with his hand. At intervals he did this with extreme violence, keeping on for half an hour, an hour, or longer. Such bouts were quickly followed by oxyhæmoglobinuria, and this was always the case, and restraining the patient from beating his forehead tended to reduce the number of the paroxyms. The amount of hæmoglobin lost was equal to that contained in from 1.5 to 2 grams of the patient's blood. The authors suggested that the violence caused extravasation into the subcutaneous tissue, and that the hæmoglobin rapidly passed out of the red cells, owing to the local development of an antolysin and entering the blood stream, was filtered off by the kidneys.

To this surmise it may be objected, as Dr. Sambon remarked that the authors found no appearance of bruising even "after severe beating." He was inclined to regard the patient's violence as an accompanying phenomenon. He thought a more specific cause must be sought. Dr. J. W. W. Stephens compared the case with blackwater fever. Dr. V. Harley suggested that vibration might liberate the hæmoglobin from the stroma of the corpuscles. Dr. A. E. Garrod thought the formation of a hæmolysin more likely than friability of corpuscles. Dr. Bulloch said hæmolysis might occur from such substances as ether, or from more complex animal products, *e.g.* cobra poison. Dr. Barratt, in his reply, held that proof had been given that the attacks were due to traumatism. By grinding up the blood cells with salt-solution in a mortar they failed to liberate hæmoglobin, and that was against the vibration surmise. There was no apparent bruising, and yet the prolonged violence must have given rise to extravasation. It is only now and then that the subsequent history of cases exhibited at the societies are recorded. But at the Medico-Chirurgical Society, on the 24th ult., a report was made on the remarkable cases of molluscum fibrosum in three children, communicated by the late Dr. John Murray as long ago as 1873. Drs. A. H. Robinson and A. Whitfield stated the sequel. The three patients of Dr. Murray were two girls and a boy, who had then numerous tumors, varying in size from that of a pea to a walnut, scattered over the head, face, ears, back, and extremities. Similar growths were found on the gums. The terminal phalanges of the fingers were buried in purple growths. The youngest, aged two years, has now been dead some time, and no further account is obtainable. The eldest, a girl of seven years at that date, had lived in a home for some years and was visited this year. The boy died in an infirmary, and photographs and material for microscopic examination were obtained.

The chief change noted on visiting the female is enormous growth of the tumors in size. Some are described as lobed masses larger than oranges, those on the ears as the size of the fist, one or two new ones have appeared, and one seems to have disappeared during these years. Her head is so disfigured that she keeps it wrapped up in linen. In the male, also increase of size had gone on, and many smaller subcutaneous tumors had formed about the fingers and toes. Histologically, the tumors proved to be fibromata—not neurofibromata. Those from nose and ear blended with the corium and might be called cutaneous—the one from a finger was distinctly subcutaneous. Sir Thomas Barlow said he had had these cases under observation for years after Dr. Murray's death. The father had malignant disease years after their birth. The children were mentally defective. They had febrile attacks at times, when the growths increased in size, but not always. As we are extending our "tube" railways, considerable interest attaches to a report on the microorganisms found in the air of the present "tube" prepared for the County Council and issued by that authority on Wednesday. The report seems fitted to discount most of the loose statements made by the sensational papers. Taking the results of all the experi-

ments, Dr. Andrews does not seem to have found a very great excess of microorganisms in the tube over that of the air outside—the exact proportions being as 13 to 10. The chief excess was in the carriages and lifts and stations —in fact, just where the passengers were most crowded. The air of the tube, in fact, did not compare unfavorably, so far as microorganisms are concerned, from the air to be found in most inhabited rooms.

The City of Westminster has adopted a scheme of voluntary notification of tuberculous disease of the lungs.

The Chelsea, Brompton, and Belgravia Dispensary held its ninety-first annual meeting last week. At that ripe age and locality in an improving quarter it seems to have fallen on bad times. The subscriptions are so scanty that it has been necessary to make an important change or give up its work, accordingly it has adopted the provident system, and is erecting a new building at a cost of £2,500, for which an earnest appeal is made to the charitable. But why should charity be invoked at the moment when all pretense of charity is being abandoned?

Surgeon Major-General W. R. Rice, M.D., C.S.I., died on Friday, in his seventy-first year. He had served in the army from 1843 to 1877. He was in the Crimea and afterward throughout the Central Indian Campaign, receiving the medal with clasp and brevet of major.

Dr. Thomas Sowerby of Welshpool, died on the 25th ult., at the age of eighty-one years. Another octogenarian, whose death is announced at eighty-seven years, is Dr. Paddon, J.P. He retired from practice many years ago. He took his degree in 1840. Dr. J. Adam Hunter of Edinburg died on the 28th ult., in his eightieth year.

OUR PHILIPPINE LETTER.

(From Our Special Correspondent.)

SANITARY CONDITIONS OF HONGKONG—NEW QUARANTINE STATION FOR MANILA—NEW AMERICAN STEAM LAUNDRIES—DAILY BATHING IN MANILA.

Dr. J. C. Perry, U. S. Marine Hospital Service, who has been in charge of the quarantine service at Manila for the past three years, has just been ordered back to the United States for duty. He will be relieved by Passed Assistant Surgeon U. G. Heiser, Marine Hospital Service, who has just arrived by way of Egypt, where he was the representative of his department at the international convention on tropical diseases, and after a short stay in India, where he investigated the question of cholera and bubonic plague. With Dr. Heiser, who came to Manila via Hongkong arrived Dr. J. S. McMillan, the U. S. Marine Hospital Service physician stationed at the latter city, who came for the purpose of satisfying himself as to sanitary conditions in the Philippines and arriving at an understanding with the quarantine officers here.

Sanitary conditions in Hongkong have a close relation to the public health in the Philippines, by reason of the great amount of traffic between Hongkong and Manila and the short distance between these ports. Steamers make this distance, 600 miles, in two days, and sailing vessels in twice that time. Many Chinese are continually going back and forth, and much merchandise and foodstuffs are constantly being brought into Manila for their use. The occasional imp rtation of plague infection into Manila can thus scarcely be prevented by ordinary methods of quarantine. While the late development of plague and cholera in Manila was undoubtedly due to relative inefficiency of the Manila quarantine service, the quarantine officials cannot be fairly judged as to the quality of their work, except in the light of a full knowledge of the geographical relations and existing sanitary conditions of Eastern Asia. That Dr. Perry and his excellent assistants were able to keep the original infections out for so long a time, and to prevent the introduction of new infections since these diseases first gained entrance, is just cause for hearty praise. If plague could not be kept out of San Francisco—three weeks from infected points by the fastest steamers and in communication with them by only relatively few boats—it was scarcely to be expected that Manila, within easy reach by small boats of a hundred infected points, and with a quarantine service which the shortness of the time since the abolition of Spanish sovereignty scarcely permitted to be brought into a perfected condition, would be able to escape unscathed. Japan, with its highly efficient and thoroughly organized quarantine service, lying at a greater distance from the infected ports, possessing a climate far less favorable than that of the Philippines for the multiplication of germ life, and with a peaceful population possessing the highest respect for laws and official control, has suffered to no small extent from both plague and cholera. Bearing these facts in mind, one cannot but feel that the quarantine officers in the Philippines deserve the highest credit for what they have accomplished in spite of the geographical and climatic obstacles already mentioned, combined with the existence in the Philippines, until lately, of a state of insurrection and anarchy.

The newly constructed quarantine station for Manila, located at Mariveles, at the entrance to Manila Bay, is most comprehensive in plan and complete in detail and equipment, and is a monument to the energy and ability of Passed Assistant Surgeon Perry, U. S. M. H. S., who carried out the work of its construction during the troublous times of the insurrection, and in addition to the performance of his arduous duties as Health Officer of the Port of Manila. The cost of construction of the buildings of the disinfecting station, isolation camp, and hospital amounted to $210,000. Under Spanish rule a quarantine station had been maintained at Mariveles, but the buildings were so old and the station so poorly planned and equipped as to be of little value in the work of reconstruction. Of these old Spanish buildings but two have been preserved, and these are used for offices, storerooms, and officers' quarters.

Mariveles quarantine is distant thirty miles from Manila and directly inside the entrance to Manila Bay. It is located at the end of Mariveles Bay, a small harbor completely sheltered on nearly all sides by high mountains, having a sandy bottom, and affording perfect protection and anchorage. At low water there is a depth of thirty-five feet at the end of the short station wharf, so that the largest vessels can readily come alongside the disinfecting station. There is an abundant water supply of unimpeachable quality, piped from an uninhabited and uncultivated water shed three and a half miles away and delivered under sufficient pressure to throw water over any of the buildings of the station in case of fire. The disinfecting plant is completely equipped with bichloride tank, sulphur furnaces, fixed and portable formaldehyde generators, and two steam sterilizing chambers. There are ample disrobing rooms for the steerage passengers, and fifty shower baths for this class of passengers. On leaving the shower baths they receive cotton pajama suits and pass into the waiting-room, where they remain during the disinfection of their clothing. Before entering the bath-house each passenger receives a numbered tag, which he ties around his neck during bathing. Any valuables he may have are placed in a box having the same number and he is given a sack bearing the same number, into which his clothing is put after disrobing, and in which it is carried by an attendant to the disinfecting chamber; where it is exposed for twenty minutes to superheated steam at 240° F. At the end of this time the sack is taken out and returned to the passenger, who has finished his bath in the meantime. By this means, articles are promptly returned to the owner without the loss or confusion incident to their becoming mixed with art cles belonging to others. Shoes are disinfected by being dipped in bichloride solution. As the Chinese are particularly averse to bathing, attendants remain in the steerage bath-room to see that each person properly bathes himself with a sufficient use of soap. Two smaller bath-houses are provided for the bathing of first and second-class passengers. In these the arrangement is somewhat different, there being a number of small disrobing and dressing rooms with the shower baths between. As some of the first-class passengers seem to delight in trying to evade the bath, an arrangement is being tested by which a passenger, on entering the bath-room, steps on a movable floor, which turns on the shower bath automatically, and thoroughly wets the passenger, who might then just as well continue the sometimes involuntary bath to which he has been subjected. General waiting-room, with comfortable chairs and reading matter, are provided in these smaller bath-houses As the whole plant is built on piles over the waters of the bay, the dirty bath water, excreta, etc., create no difficulty as to their disposal. Two medical officers and about twenty-five men, of whom sixteen are Filipinos, form the personnel attached to the station. To show the efficiency of its operation, it may be mentioned that a large army transport with more than a thousand passengers aboard has been disinfected throughout in but ten hours.

At the head of the wharf on shore are located the buildings of the detention camp hospital and offices. These, like the buildings of the disinfecting station, are well constructed of hard wood. The building for first-class passengers is of two stories, well-ventilated and provided with small bedrooms on each side of central corridors, each room having two beds and a window. The buildings for the steerage passengers are so arranged as to divide the passengers into five groups of two hundred persons each; no one group having any contact with another. The buildings are comfortable one-story affairs, with the kitchen in a semi-detached out-building. Bunks are constructed in three tiers, and split

bamboo frames rest inside these bunks and form very comfortable beds. High fences of barbed wire separate each group and these are so laid out that a single watchman guards the yards of all five groups. A small army post is located just outside the quarantine reservation, and the soldiers are used for guard duty and to enforce the maintenance of quarantine. The whole station is amply shaded and very attractive, while the cool sea breeze, which always blows, makes the climate far more pleasant than that of Manila. The Filipino attendants are said to be very efficient, even more so than the ordinary class of whites, as the pay given is so high as to secure the very best class of native labor. As Mariveles is shut in by an almost uninhabited and mountainous country, there is practically no communication by land, and its site for a quarantine station could hardly be improved. The station cannot be commended too highly. It is far better than the quarantine station at San Francisco, or many United States cities, and is surpassed by few. Its creation by Dr. Perry is a work which ranks favorably with the best improvements made by the United States in the Philippine Islands, and one of which Americans may justifiably be proud.

The United States Marine Hospital service here has not limited its good work to Manila, but now that the main station has been established at Mariveles, it is going ahead with the work of organization of stations at the six ports of entry for the Philippine Islands. Marine Hospital surgeons have already been stationed at several of these ports, and others will be assigned as soon as their services for these islands become available. These men will be able to do much toward preventing future epidemics of cholera, and to limit the dissemination of the plague infection now in Manila. Their assignment to stations in the southern islands is very important, in view of the trade relations with Borneo and Singapore. The fact that the previous disastrous epidemic of cholera in the Philippines began from an infection brought into Jolo from Singapore—always an unclean port—should not be forgotten.

While on the subject of quarantine in this part of the world, mention must be made of the methods in vogue in up-to-date Japan. The quarantine regulations of that country are largely modelled after those of the United States, as are their quarantine stations. The quarantine rules are most strict, as they necessarily must be with Chinese and Corean pestilence centers only two or three days away by steamer and much commerce being carried on by the Japanese with ports on the mainland. The Japanese are thoroughly imbued with the idea that it costs less in lives and money to keep out a disease than to stamp it out after it has once secured a foothold. For this reason, and possibly also because they feel that their modern civilization is on test with foreign nations, they carry out their quarantine rules with strictest detail. On entering a Japanese harbor a boatload of quarantine doctors comes alongside, their quarantine launch being equipped with microscope and accessories for the purpose of making any desired bacteriological examination on the spot. Besides their own language, each of these doctors is able to speak at least one foreign tongue, so that English, French, German, Russian, Chinese, and other nationalities can be questioned in their own language. Every passenger and member of the crew is lined up on deck, called by name, and the total number verified. While this is going on, the other physicians pass along the line, feel every man's pulse, make him put out his tongue, and if he shows any appearance of sickness they produce thermometers and take his temperature.

Nothing escapes them, and it is useless to try the old dodge of sending a man around the deck-house to be counted twice, for the place where every man not in the rank can be found must be stated, and these men are inspected and their condition verified while the count on deck is going on. It is also useless to expect that the condition of a sick man, sent on deck, will not be noted. Such men are set aside and carefully gone over by several of the quarantine doctors in a way which show their proficiency in the latest methods of diagnosis and familiarity with modern diagnostic appliances. The disinfecting stations, as already mentioned, are modelled after those of the United States, but the Japanese go us one better in that, after the bath, any drinks desired, except champagne, are served to the first-class passengers at the expense of the Japanese Government. So carefully are the quarantine regulations observed in Japan that complete inspection of the crew is carried out even where vessels are making short runs from one port in Japan. Thus a vessel touching at Nagasaki and arriving at Kobe a day later, would be again completely inspected, and returning at once to Nagasaki would be reinspected at the latter port with every detail required in the original inspection made on arrival from Shanghai or other infected port.

There is a fairly efficient quarantine service in the French colonies of Tonkin and Annam. In the English free ports of Hongkong and Singapore every effort is made to attract commerce. The sanitary inspections are perfunctory and the quarantine regulations lax perhaps also to some extent as a result of the great difficulty of controlling the movements of small native craft. In British Borneo the country has not developed to the point of an efficient quarantine service; one is in operation at Sandakan, but it exists more in name than fact, at that port. The quarantine system at the Russian ports in Siberia and Manchuria is good, but not so thoroughly carried out in detail as in Japan. The Germans have been established such a short time on the Shantung coast of China that it is hardly fair to judge their system at the present time. Of course, under the Chinese and Corean governments the ports in those countries possess no quarantine service of any kind.

Because of the uncleanly habits and improper methods of washing of the native laundresses, the two American steam laundries in Manila are proving a great boon to the foreign population. One of these laundries is a purely commercial enterprise, which has not been a thorough success because of bad administration. The other establishment is owned and operated by the Army Medical Department. It was established primarily for the laundering of the linen of the various hospitals and transports, but also laundry clothing for persons connected with the military service. At present, with the army hospitals much reduced in size, it gives employment to about fifty men, and laundries from 75,000 to 85,000 pieces per month. The clothing is all disinfected and boiled, and everything carried out in approved sanitary style. Since the establishment of this government laundry, the prevalence of "dhobie itch" and other parasitic skin diseases has been greatly reduced among the soldiers. Lately a number of small post laundries have been established and operated by the military authorities at a number of outlying stations. This was necessary in view of the fact that the infections of smallpox, cholera, and other diseases were frequently introduced among troops where clothing was scattered periodically through the insanitary native dwellings for laundering. These post laundries are under careful supervision and sanitary inspection. The clothing is boiled and the work carried out in a proper manner. There is no doubt but they have done much to prevent the occurrence of infectious diseases among the soldiers, as well as proved of financial benefit to them.

Judging superficially, the Filipino would seem to be a paragon of bodily cleanliness, for one of the most striking features of native life in these islands is the bathing of the person and washing of clothing which constantly goes on along every watercourse. From early in the morning until the sun gets high the shores are lined with women washing clothing, while late in the afternoon whole villages turn out for their daily bath. Unfortunately, for proper results, however, this energy is misdirected, with the result that a properly bathed native, or clothing clean from a sanitary standpoint, is rarely seen. The Filipino seems to care nothing at all for the character of the water in which he washes his clothing or person, and is as likely to resort to a filthy estero, acting as an open sewer, for this purpose, as to utilize a more cleanly water supply. The waters of the Pasig river, as it flows through Manila, receive all manner of filth, slops, dead animals, human excrement, and all kinds of organic refuse. At certain stages of the tide the water has the appearance, odor, and qualities of dilute sewage, yet hundreds and thousands of natives resort to it for purposes of cleanliness. The incongruity of attemping to purify clothing by washing them a few feet from where a house drain discharges its foul contents, or the river receives a constant addition of fecal matter from overhanging privies, never appears to strike the Filipino. Soap is but little used, but the garments are soaked, struck against a flat stone, beaten with a paddle, and spread out to dry on the dirty ground or over a flat bush. Clothes lines are almost never employed. As the clothing is never boiled and the germs of parasitic skin diseases, particularly "dhobie itch," seem to be omnipresent in the islands, garments washed in this way are certain, sooner or later, to convey skin disease to the wearer. One has only to watch the constant scratching of their persons by the natives to appreciate how prevalent parasitic skin diseases are among them, and where American soldiers are forced to depend upon the natives for the performance of their laundry work a large proportion of them contract tinea and other skin affections.

The average Filipino probably bathes the entire person at least once daily. This is a relatively easy matter, as water of some sort is usually available and the natives are

not encumbered with many clothes, or a high sense of modesty. In the country districts, men, women, and children often strip naked and bathe in the stream together, although the women sometimes wrap a strip of cloth about the loins. They seem to wash themselves most carefully, but soap is almost never used, and as a result the skin is not properly cleansed. Usually a native is perceptibly dirty about the neck and back of the ears. Sometimes a certain native root is mashed up in water and used to shampoo the hair, but generally cocoanut shells full of water are merely poured over the latter. As a luxuriant head of hair is the pride of these people, and as the hair is kept constantly greased with cocoanut oil, pouring water over it without the use of soap has about the same cleansing effect as pouring water on a duck's back. As a result of saturating the hair with cocoanut oil, seborrhœa is very rare among the natives, but as the oil soon grows rancid it imparts an unpleasant odor to the native and his immediate surroundings. The smell of rancid cocoanut oil probably pervades every native house in the Philippine Islands, so universal is its use for cosmetic purposes. On the other hand, while kept free from dandruff, hair greasy with cocoanut oil cannot be properly cleaned and soon becomes infested with head lice. A common domestic scene is to see three or four native women squatting down and carefully picking the lice out of each other's hair, and it is a common saying that where a native lies down lice rise up.

Although particular about the daily bathing of the body, the natives are not as particular about the frequent washing of the hands, which, from the filthiness of the surroundings of the Filipinos, are usually very dirty and liable to convey the germs of infectious disease or the ova of animal parasites. The finger nails are rarely kept in a cleanly condition. The teeth receive little care, but seem firm and resistant, to which it is said that the prevailing habit of chewing betel nut contributes in no small degree, though the teeth are discolored thereby.

ANTISEPTIC RULES FOR MONTHLY NURSES.

To the Editor of the Medical Record:

Sir: Apropos of the discussion on puerperal septicæmia, at a recent meeting of the Medical Society of the County of New York, I subjoin hereto a card* entitled "Antiseptic Rules for Monthly Nurses," that I have found of the greatest value in my obstetrical work.

I keep a supply of these cards on hand; one of them is given to the nurse in attendance on the case for her instruction and another to the patient who, by frequently consulting it, may be able to see that the nurse faithfully carries out its provisions.

The card and the method were the suggestion, years ago, of Dr. Playfair and, though slightly modified, are retained almost in the original form recommended by this eminent obstetrician.

Since I have employed this practical means of instruction to patients and to nurses I have had much less trouble in the conduct of my obstetrical cases.

Of course, the card may be altered or extended to suit the judgment of the practitioner—its design and invariable use that will go far toward diminishing the liability to septicæmia in puerperal cases, and hence remove much of the anxiety of the obstetrician who can not be always at the bedside of his patient, are the essential considerations.

Respectfully,

Henry K. Leake, M.D.

Dallas, Tex., April 8, 1903.

*Antiseptic Rule for Monthly Nurses.—(1) Nurses are not permitted to examine patients. (2) Before attending patients, nurses must take bath and change clothing. (3) Nurses must not go directly from septic cases to others, either before or during delivery. (4) Lysol is supplied to each patient. Solutions are made by adding one tablespoonful of lysol to two quarts warm water. (5) Hands and forearms are thoroughly scrubbed with soap and warm water and then soaked for five minutes in lysol solution. (6) A small basin containing lysol solution (frequently changed) must always stand by the bedside of the patient, and the nurse must thoroughly rinse her hands in it every time she touches the patient in the neighborhood of the genital organs for washing or any other purpose, before or during labor, or for a week after delivery. (7) Vaginal pipes, enema tubes, catheters, etc., should be thoroughly scrubbed and boiled before use. (8) Unless express directions are given to the contrary, the genitals should be sponged with warm lysol water twice daily, morning and evening, for two weeks after delivery. (9) All soiled linen, diapers, etc., should be immediately removed from the bedroom, and no old cloths used about the patient—cotton is supplied for this purpose. The latter is kept in place by a "square" of new cheesecloth.

N. B.—These rules are for the protection of the patient from the risk arising from accidental contamination of the hands and sponges. It is expected that they will be faithfully and minutely adhered to.

THE QUININE TREATMENT OF CHOLERA

To the Editor of the Medical Record:

Sir: Notwithstanding the fearful mortality of the recent epidemic of cholera in the Philippines, approximately two hundred thousand cases with one hundred and forty thousand deaths, I wish again to affirm that the disease is nearly as easy to treat successfully as is pernicious malaria, and by the same remedy. Moreover that the effect of quinine in cholera is much more promptly apparent than it usually is in malarial disorders, as the vomiting and purging are controlled in an hour or two after the administration of fifteen or twenty grains of the drug, and thereafter the treatment may be *pro re nata*. The quinine must be given by the mouth, of course, as its emunctory is the kidneys, and when given intravenously or hypodermically it does not reach the intestinal tract, the sole habitat of the germ in the human body. *It was the hypodermic syringe that killed the treatment.* While willing to give all credit to men of greater attainments in the *science* of medicine, I deny that any one is better able than myself to judge of the effect of a remedy in disease, be it quinine in malaria or quinine in cholera. It is nearly thirty years since I treated cholera in its latest, and it is to be hoped last, invasion of the Ohio Valley, where we have had it more frequently and for more years continuously than in any English-speaking territory of like extent, but I have never for a moment forgotten the prompt cessation of symptoms and the prompt reaction that occurred, even when the disease was well advanced and in malignant form.

Dr. H. C. Wood notices the treatment in the ninth and tenth editions of his "Therapeutics," and Dr. John V. Shoemaker in all recent editions of his "Materia Medica and Therapeutics." It seems to me impossible that any unprejudiced medical man can read the articles on this subject in your issue of October 1 and December 10, 1892, and more especially that of April 29, 1893, or, the whole matter epitomized in the *New York Medical Journal* of August 18, 1894 without being convinced that the better treatment of cholera has been discovered more times than America or than anæsthesia.

The quinine treatment has, I believe, been wholly overlooked in the Philippine epidemic, resort being had mainly to salol and tannin enteroclyses. If these gave a result of 48.4 per cent. mortality in Hamburgh hospitals, where all appliances for their use were at hand and physicians and skilled nurses for their employment, what result may be expected where a country physician must ride miles in one direction to see a cholera patient and then as far in the opposite direction to visit another? Moreover, before the last European epidemic was over the treatment was discarded and resort had to the beggarly element of chamomile tea.

My claim for the quinine treatment is that, from a scientific standpoint, it should be of all remedies the best in the disease, and that when given in proper doses, by the mouth, it has done all that could be expected of any remedy in curing it. In support of this claim I offer not my own experience alone but the united unfaltering testimony of good men and true in every epidemic from 1831 to 1873 inclusive.

Erskine B. Fullerton, M.D.

Columbus, O.

HOW TO REMEDY THE EVILS OF THE MEDICAL PROFESSION.

To the Editor of the Medical Record:

Sir: The apathy of medical men in regard to the evils besetting the medical profession is astounding. Here is, for example, the dispensary evil. According to the report of the Committee on Dispensaries of the State Board of Charities, there were treated in the dispensaries of Greater New York, in 1901, not far from a million patients! If we consider hospital treatment in addition, over a third of Greater New York gets free treatment yearly, and this in spite of the Dispensary Laws.

There is also the contract practice in lodges and societies, which, on the East side of New York, has reached incredible proportions. Thus, for instance, on the East side, physicians enter into agreements with associations, of various kinds, which are very numerous in New York, to treat every member with the whole family at the rate of two dollars a year! Nay, some physicians even offer their services free, just on trial! And the competition among the doctors to get elected as a physician to a lodge

or society is so keen that they must resort to electioneering, and very frequently they follow the methods of the ward politicians.

It is hard to see what can be more detrimental and disgraceful to the medical profession as well as to the community at large. The doctors who get the lodges and societies work themselves to death for very little remuneration, and those doctors who cannot get them have nothing to do. Thus there is demoralization on all sides.

Here again, for example, is the Board of Health. The community, by the way, seems to have such a poor opinion of physicians that the Charter of Greater New York debars a physician from being a president of the Board of Health of New York, on the plea that physicians lack executive ability! A physician can be a prime minister of France or a governor of Cuba, but not a president of the New York Board of Health! And the doctors holding these inferior positions are treated like medical clerks. Under the former administration they had to curry favor with the district leaders in order to get and to hold their positions, and now they must get the good graces of other powers. Thus many doctors who had been connected with the Department of Health for years were removed on the plea of lack of funds; at the same time, however, new men who had been only recently appointed were retained, and this in spite of the civil-service laws. The doctors in the Health Department are ordered about, scolded like school-boys, spied upon, punished for trivial offences by being given extra work, or they are entirely removed, just as it pleases the powers that be. Of course this demoralizes them, instead of making them render services worthy of a physician.

This shows how terrible the condition of the medical profession is, when doctors are found who are willing to undergo such humiliations, which even foreign unskilled laborers would not stand for a day.

I therefore respectfully suggest that the following measures be adopted in order to improve the condition of the medical profession in New York, and I say in New York, for we must begin here first: (1) That physicians in dispensaries be paid by the city a reasonable amount, the same as are teachers, policemen, etc. The fact that doctors are found who are willing to give their services free is no justification for the city to take advantage of it. As things stand now, the really poor do not get proper attention in the dispensaries, as, with some exceptions of course, the dispensary doctors prefer to work up a class of well-to-do patients in the hope of getting them as private patients at his office. If dispensary physicians were paid, the dispensary laws could be strictly enforced. From $500.00 to $600.00 yearly would be a reasonable sum to pay a doctor in a dispensary. The whole amount would be less than a million dollars, and there is no earthly reason why the city should not pay so much in order to give medical treatment to those who need it. (2) That lodge and society practice be declared by the medical societies to be un-ethical, the same as is advertising in the newspapers. And (3) which is the most important, that the control of medical matters in New York be in the hands of a board of medical men elected by the several medical societies of New York; that appointments to dispensaries be made by said board, on competitive examinations, and that the control of the Health Department be also in the hands of said board. I would suggest that only heads of classes in dispensaries be appointed, on competitive examinations, and be paid, and that assistants be allowed to attend without examinations, in order not to debar from the opportunities for clinical observation those who do not care to take the examination. Of course consultants should also be appointed, who, it is needless to say, are to render their services free.

These measures can easily be realized if the several medical societies of New York would take up the matter. And subsequently there can also be introduced needed reforms in the appointments to positions in hospitals and colleges, but at first it would be unadvisable to undertake too much.

Such an arrangement would create many openings to able young men, and the congestion in the medical profession would be somewhat relieved. The deserving poor would be properly treated; and the dispensaries would become centers for real scientific work instead of means for getting private patients, and the whole tone of the medical profession would thereby be raised. At the same time the benefit to the public at large would be incalculable, for the health and the lives of the public being in the hands of the medical profession, the elevation of the latter redounds to the benefit of the former.

Progress of Medical Science.

The Boston Medical and Surgical Journal, April 16, 1903.

Variation in the Composition of Human Milk.—Philip P. Sharpless and Eugene A. Darling state that the average composition of human milk as shown by 117 analyses, is: Fat, 2.91; sugar, 7.01; proteids, 1.34; ash, 0.13. Total solids, 11.39. Solids, not fat, 8.48. There are wide variations from the average in milk from the same individual at different items. There are marked variations in the average composition of milk from different individuals. The average composition of human milk does not vary to any marked extent at different periods of lactation. During the first lactation, the milk, on the average, is weaker in fat and proteids, but stronger in sugar than in subsequent lactations. These differences may or may not be due to age.

Cream for the Home Modification of Milk.—Charles W. Townsend gives the following conclusions of his studies into the subject: (1) Centrifugal cream is probably less desirable for infant feeding than gravity cream. As obtained from dealers it is often far from accurate in percentage. (2) Siphonage for obtaining gravity cream is an accurate method, but one requiring considerable skill to perform accurately and safely. (3) Dipping off the top milk is an accurate and safe method if reasonable care is used. (4) The method for obtaining gravity cream by pouring off the top is very accurate and extremely simple. There is no instrument to be bought and kept clean. By this method it is possible to obtain cream of any desired percentage up to 26 per cent. (5) To ensure perfect accuracy frequent examinations with the Babcock machine are required; but for practical purposes this is not necessary, provided the mixed milk from a well-regulated dairy is obtained.

Trikresol in Para-urethral Abscess.—M. L Heidingsfeld reports four cases of para-urethral abscess which he treated by the hypodermic injection of trikresol. An ordinary 15-minim glass syringe, provided with a retaining screw was used, and after it was filled with the remedy was armed with a 26-gauge needle; the air was expressed, and the retaining screw run down until the fraction of a minim could be carefully measured by adjustment of the retaining screw. The proper dose could then be estimated, a drop the size of a bead sufficing for the smallest abscess, and a minim or more for the larger ones, and then injected into the center of the abscess. In all four of these well-defined cases, not only was there a complete cure of the abscess in from seven to fourteen days, but in three of the cases there was cut short an exceedingly obstinate, refractory, and unduly protracted gonorrhœal urethritis. In two of the cases it effected a prompt and complete cure of the abscess when radical extirpation, free incision, and drainage, and the free use of the actual cautery, measures which find a very esteemed and valuable place in the therapy of some of the most successful and celebrated genitourinary surgeons, utterly failed. Although four cases scarcely afford sufficient experience to determine the full efficiency of the preparation in all cases and under all conditions, yet the marked success which attends its use in analogous conditions, pustular acne, and furunculosis, its ease of administration, and the absence of any marked distress or serious, complication, thoroughly suffice, in the author's opinion, to warrant its use in every accessible case, until its efficacy, unfailing or otherwise, is fully established.

American Medicine, April 18, 1903.

Angioneurotic Purpura.—Raymond Wallace speaks of the unsatisfactory etiology of this affection. He divides the causative factors into three general classes: infectious, toxic, and vasomotor. The exact pathology of this condition is unknown. The symptom complex, although not characteristic, may be summarized as follows: Relapses or recurrences extending over several years, cutaneous lesions of a clearly purpuric nature; gastric crises, intestinal crises, pain, vomiting and diarrhœa; marked general hyperæsthesia with an angioneurotic œdema of extremities and face; hemorrhages from the mucous membranes; the blood picture of a pernicious anæmia.

Limitations of the Dimethylamidoazobenzol Test for Free HCl in the Stomach Contents.—Wilbur F. Skillman presents the following conclusions: If the test for lactic acid is positive, Gunzburg's or Boas' reagents or some other method should be used to determine whether our dimethyl reaction is due to lactic acid or to free HCl. If the stomach is normal both as to size and position and the peristaltic function is unimpaired, then dimethyl will give fairly accurate results. If the size and position of the stomach are not normal, or if the peristaltic function is delayed, then Gunzburg's or Boas' tests should be first performed

o test positively whether free HCl is causing the reaction r whether it is caused by organic acids, before proceeding o titration with dimethyl.

Bacteriologic Studies of the Skin and Th.oat in Cases f Scarlatina.—George H. Weaver concludes: The bacteria obtained from cultures from the skin, epidermic cales and the surface of the tonsil in cases of scarlatina re the same as those found in the same locations in health, nd no one of them is constantly present except the treptococcus in the throat. Because of the numerous occi which grow in such cultures, and which appear in roups of two and four or bunches of the same under the icroscope, it is impossible to identify them, except by a omplete study in pure culture. Cultures made by inexerienced persons or by those who do not fully appreciate he importance of avoiding the tongue are especially apt o contain large diplococci or sarcinæ. The streptococcus s present upon the tonsil of scarlatinal patients in enorious numbers in almost all cases.

Medical News, April 18, 1903.

Notes on Systemic Infections by the Staphylococcus ureus.—E. Libman states that children with systemic taphylococcus aureus infection are apt to have the bones involved, whereas adults with a similar infection are ore liable to have other forms of metastatic lesions. n the twenty-three cases in which this organism was ound during life, the finding has been confirmed in every stance. In 330 other blood cultures not a single colony f this organism has been found. Out of the twentyhree cases, five recovered. It is generally considered hat the more bacteria there are found in the blood the ss chance there is of recovery. This does not necessarily old good. The number of bacteria found depends, in me cases at least, upon the time at which the examinaon is made, as the great tendency is for the body to d itself of bacteria and for metastases to be established.

A Brief Review of Some of the Etiological Factors in ntestinal Dyspepsia.—E. Franklin Smith declares that ntestinal dyspepsia may be due to abnormalities of seretion of absorption, or of peristalsis. Among the redisposing factors are age, sex, and occupation. It is ost common between thirty and forty, and before ten. t is more frequent in males. Heredity plays an imortant rôle here. Previous attacks predispose to others. Iental labor predisposes to this affection. Exciting auses are pathologico-anatomical alterations of the ntestinal walls, nerves, lymphatics, or blood vessels; bsence or deficiency of the intestinal digestive secreons, especially of bile and pancreatic juice; qualitative r quantitative irregularities of diet; abnormal bacterial ctivity; abnormal gastric chemistry; abnormal subtances or irritation, reaching the intestines from the lood; activity of the intestinal parasites, worms; hyerperistalsis.

The Rational Treatment of Tetanus: A Report of uccessful Treatment by Spinal Subarachnoid Injections f Antitetanic Serum.—W. H. Luckett concludes that he shock or collapse so often following spinal subarachoid injection of cocaine for anæsthesia is not due to n upsetting of the equilibrium of the pressure in the pinal canal, but is due solely to the physiological action f the cocaine. Given a wound infected with tetanus, he writer is by no means positive that the anatomical eat of the wound does not play an important rôle in he production of the constitutional symptoms of tetanus. ccording to present views, any wound infected with etanus near a large nerve will be more likely followed y constitutional effects of the infection than a wound natomically remotely removed from the seat of a large erve. The writer believes in the spinal subarachnoid njection of the tetanus antitoxin, preceded by the withrawal of the active, concentrated, highly toxic spinal uid, supplemented by forced nutrition and proper care f the wound.

New York Medical Journal, April 18, 1903.

The Treatment of Some of the Surgical Complications n Typhoid Fever.—J. F. Erdmann discusses hepatic nd subphrenic abcesses, cholecystitis and perforations f the gall-bladder and intestines. From statistics hich he presents, he is inclined to believe that in cases f intestinal perforation we should not give more than hree or four hours for the shock to subside before operting. The suture to be employed is either the Lembert r the circular purse string when inversion is possible. he question of drainage can only be arrived at by experience. Erdmann is inclined to believe, if we can make fairly clean toilet, no drainage should be used, as we ly rely upon the leucocytes taking the same course ere as in our work in appendicitis and septic peritonitis ue to other causes.

The Work Performed by the Diagnosis Laboratory of the Department of Health in Connection with Ehrlich's Diazo-reaction During 1902.—This report is made by J. S. Billings, Jr., who concludes as follows: (1) The examination of the urine in cases of suspected typhoid fever is of value, provided that its limitations are recognized. (2) While not so absolutely pathognomonic of typhoid fever, yet the diazo-reaction is even more constantly present in that disease than the Widal reaction. So that its absence at a period when it should be present, if the case is one of typhoid fever, is of considerable value in making a negative diagnosis. (3) In a majority of instances the diazo-reaction is present in the urine at least forty-eight hours earlier than the Widal reaction in the blood. (4) It disappears much earlier than the Widal reaction, however, and negative results obtained later than the second week are of little or of no value. (5) "Doubtful reactions" have slight significance.

The Therapeutic Value of the Röntgen Ray in the Treatment of Pseudoleucæmia.—N. Senn reports two cases. He says of the disease that he has never known a case to be permanently cured by either medical or surgical measures. He has seen intercurrent erysipelas temporarily reduce the size of the affected glands. The *x*-ray was used with great benefit in the cases reported. Constitutional disturbances following the treatment and setting in simultaneously with the progressive diminution in the size of the glands were due to a toxæmia caused by the absorption of the products of degeneration of the pseudoleucæmic product. This toxic condition unquestionably was likewise the cause of the increased enlargement of the spleen noted after a second series of applications. Senn says that there can be no doubt of the curative therapy of the rays in pseudoleucæmia.

Journal of the American Medical Association, April 18, 1903.

Bromide of Ethyl in Adenotomy and Tonsillotomy.—A. R. Solenberger gives the following rules for administration of the remedy: Do not use bromide of ethylene; do not use an old or impure solution; do not administer it in small and repeated quantities; give *en masse;* admit no air; do not continue its administration longer than one minute.

Transplantation of Omentum in the Operative Treatment of Intestinal Defects; a Clinical and Experimental Contribution.—E. J. Senn offers the following conclusions: (1) Transplantation of omentum over defects in the stomach is an established operation. (2) Transplantation of omentum over intestinal defects is recommended, but is still in the developmental stage. (3) Transplantation of omentum over defects in the cæcum is the most favorable portion of the intestinal tract. (4) Transplantation of omentum over defects in the small intestine should only be done after fixation of the segment of intestine to the abdominal wall. (5) Gauze drainage should be resorted to, excluding the general peritoneal cavity.

Treatment of Puerperal Fever.—C. S. Bacon considers this subject along conventional lines, and closes with a word on the subject of hysterectomy for this form of sepsis. He believes that its field is exceedingly limited. It is indicated only when the infection is confined to the uterus and when nature is incompetent to combat the infection. It is evident that the difficulties diagnosticated in this condition are so great that they are practically insurmountable. Therefore he believes this operation may be omitted from our list of measures to be employed in the management of puerperal fever. The surgical treatment consisting in the evacuating of a puerperal abscess, whether located in the abdominal cavity, the pelvic connective tissue or elsewhere, is, of course, indicated whenever this condition is determined.

Accessory Pancreas.—G. F. Ruediger gives five classes of abnormalities of the pancreas: (1) Those with abnormal excretory ducts; (2) the annular pancreas; (3) the divided pancreas; (4) the "pancreas minus," of Winslow, which consists of an accessory pancreatic lobule springing from the head of the main gland and extending along the wall of the duodenum, and (5) the accessory pancreas. He reviews the literature of the latter variety, reports one case found on autopsy, and discusses the theories of the normal development and the etiology of anomalies. Concerning the clinical importance of the subject, he notes that the "minus" and divided forms, although interesting from the standpoint of anatomy, are of little practical importance, as they do not bring about any serious pathological conditions, nor can they be detected during life. Abnormalities of the duct may occasionally be a factor in causing hemorrhagic pancreatitis from impaction of gallstones in the ampulla of Vater. Annular pancreas may so constrict the bowel as to cause marked dilatation above the point of constriction, or perhaps even complete obstruction. Accessory pancreas may sometimes be a

causative factor in the production of diverticula of the intestine, by exerting continuous traction on the intestinal wall, during development; or, it may at any time become the starting point of a carcinoma. This has, however, never been observed. If the swelling protrudes into the lumen of the bowel, and attains a considerable size, it might produce some obstruction to the movement of the intestinal contents; or, perhaps it might cause an intussusception by continuous traction on the inner surface of the intestinal wall, from the passage of the contents over it.

Philadelphia Medical Journal, April 18, 1903.

Pernicious Anæmia Following Thyroid Enlargement.—V. S. Merritt reports this case. The patient was a woman of forty-three years. She complained of marked dyspnœa on exertion, weakness, and enlargement of the thyroid gland. The illness began a year ago. Two years before the patient was thrown from a carriage and badly frightened, though not physically injured. In a little over a year she first noticed the enlargement of the thyroid gland. During the progress of the anæmia, the thyroid enlargement grew progressively less. In a little over two months after seeking medical aid, the patient died. There might be a question as to whether this was a case of exophthalmic goiter, followed by anæmia.

The Surgical Treatment of Tuberculous Peritonitis.—D. S. Fairchild concludes that: (1) If an intraabdominal focus of tuberculosis is diagnosed, or is suspected, an abdominal section should be made with the view of efficient treatment. (2) If a chronic tuberculosis of the peritoneum with ascites is diagnosed or believed to exist laparotomy is indicated as soon at it is found that medical and hygienic treatment has failed. (3) In fibrous tuberculosis of the peritoneum the same course should be pursued, and if cheesy degeneration has not commenced or progressed too far, a certain percentage of recoveries will follow. In acute tuberculous peritonitis with ascites and high temperature, laparotomy is useless. In extensive adhesive tuberculosis with matting of the intestines laparotomy is useless, and the attempt to separate the adhesions is dangerous in its immediate results.

Pulmonary Abscess Producing Dextrocardia; a Case Report.—Thomas L. Coley reports the case of a man of twenty-four years who was brought to the hospital cyanosed and pulseless. Foul-smelling pus was pouring from his mouth and nose. He had worked to within a few hours of the rupture of the abscess. Physical examination revealed the presence of a large cavity in the upper lobe of the left lung. Diplococci were constantly found in the sputum. The lower lobe of the left lung became solid, flat on percussion, and no breath sounds could be heard. With the increased area of dulness, the heart became displaced, and the apex could be felt in the fourth interspace on the right side, two inches from the right of the sternum. The normal heart area became tympanitic as high as the fourth rib. The tympanitic note in the downward direction, fused with that of the stomach and abdomen. At autopsy the pus-sac was found to occupy almost the whole left pleural cavity.

The Lancet, April 4, 1903.

Iodipin in Cases of Uterine Fibroid.—J. A. Shaw-Mackenzie records two cases in which this remedy was used with benefit. It is a combination of iodine and oil of sesame. It is given by injection into the tissues (buttocks) in doses of five c.c. In one case there was no local or general disturbance from the injections. In the other numerous superficial veins became visible over the buttocks, and there was a slight cough with some hoarseness. The bowels were troublesome, and the punctures became congested with slightly bruised areas. The treatment is merely one form of giving iodine. Possibly iodine may influence the vasomotor or trophic centers themselves, in addition to its presumable action on the muscle element and nutrient vessels. No particular local or general inconvenience followed the injections or treatment. At one time there were some slight induration and tenderness at the site of the puncture, but they soon passed off. Neither were there any of the disagreeable effects often associated with the administration of iodide of potassium. An irritating dry patchy eczema appeared, continuing more or less, and some darkish stains, lasting a day or two, but disappearing without trouble.

Smallpox Treated by Serum from Immunized Heifers.—R. S. Thomson and J. Brownlee give their experience with serum injections in the recent Glasgow epidemic. Regarding the influence of the injections on the symptoms of the disease, an analysis of their cases shows the following facts: (1) No action of any kind was observed in the hemorrhagic cases. (2) In certain cases in which the serum was administered from eight to eighteen days before death or commencing desiccation, no influence whatever seemed to be exercised upon the course of the disease, though in these there was ample time for the serum to act. (3) In six cases the serum was administered from four to seven days before desiccation commenced. In all of these the course was modified, and there was probably sufficient time for the serum to exercise an immunizing influence, but as all, with two exceptions, were undoubtedly vaccinated, and as these two were probably vaccinated, it is impossible to determine whether the modified course resulted from the primary vaccination or from the treatment. (4) One case showed that the serum completely failed to modify the course of a revaccination. (5) It is possible that the eruption which appeared on the eighth day after the serum was administered may have been due to the presence in the serum of some agent identical with, or closely resembling, substances present in the blood of variolous patients. (6) That the serum in one case did exercise some influence upon the tissues, though none so far as could be determined on the vaccination, is suggested by the development of the cutaneous erythema on the eighth day after the administration of the serum was begun. Details of this eruption and of its distribution are given, but the authors observe that the characters and distribution were precisely those so frequently present in the erythematous and some other of the prodromal eruptions so commonly found in variola and varicella and exceptionally after vaccination. This suggests that some active body may be present in the serum in sufficient quantity to produce a distinct reaction in the absence of variola—that is to say, when the individual has not been immunized by passing through the earlier stage of smallpox against the toxins presumably present in the serum.

The Lancet, April 11, 1903.

The Local Treatment of Psoriasis and Molluscum Contagiosum.—J. Wishart advocates the following method The involved areas are subjected to a liberal application nightly of the following ointment: 15 minims of strong solution of iodine, 15 minims of solution of carbolic acid, and one ounce of boric acid ointment, and they disappear within a fortnight. Papules are gently pricked with a sterilized needle until they bleed slightly, when a drop or two of liquor epispasticus is insinuated into each papule and also applied over its surface. This process is repeated every second night until three or four applications have been made. A small blister results in the case of each papule so treated, which, when left alone, go through the usual stages of healing attendant on any other form of simple blister. In other words, the papules are aborted and the areas of skin implicated again become normal. Illustrative cases are given.

Operative Treatment of Chronic Suppuration within the Temporal Bone.—C. A. Ballance describes in full his operative method, the steps of which may be summarized as follows: (1) The removal of the disease and the fashioning of the meatal flap; (2) one week later the epithelial grafting operation; (3) a few days (from the sixth to the ninth day) after this, and the earlier the better after the graft has taken, the removal of the dead portion of the graft as a deliberate measure, and (4) dry gauze tamponning through the meatus until the gauze comes away unstained. In three weeks the inner bony boundary is dry, and any moisture which appears on the plugs later is from the inner surface of the mastoid flap. The critical part of the healing process is thus early completed What happens afterward is of less moment. In from five to six weeks from the first operation, in the majority of cases, the operation cavity is soundly healed. The author knows of no other method which can be relied upon to give such results.

Infective Eidocarditis.—In the first Lumleian lecture T. R. Glynn considers the disease mainly in its clinical aspects, devoting special attention to etiology. In the majority of his cases he has noted general debility—25 per cent. were intemperate. Symptomatic anæmia and chlorosis must be reckoned as predisposing causes. Brights' disease may possibly predispose to this form of endocarditis. Not infrequently it follows pneumonia. In Glynn's cases there was a rheumatic history in 53 per cent. of the males and in 71 per cent. of the females; 16.3 per cent. had suffered from rheumatism within nine months of their admission. Ten—that is, 16.3 per cent.—were admitted with symptoms of rheumatism. About the same number experienced pain, with sometimes slight swelling of one or more joints during the progrd, of the fatal disorder, but these are not included among the rheumatic cases, as the arthritic manifestations may

have been pseudo-rheumatic and due to the septicæmic condition. There was post-mortem evidence of chronic disease of the heart in 83 per cent. of his patients, including 8.4 per cent. where the lesion was congenital.

Some Dangers of Hypnotics.—N. Tirard utters a caution against careless use of the this class of remedies. He says that (1) they may all involve danger; (2) the conditions under which they may procure undesirable results are not always limited upon the dose; (3) the danger may be limited to the patient; (4) it may involve the prescriber or dispenser; and (5) before the employment of a hypnotic, the bare symptom sleeplessness is perhaps the least important factor to be considered. He then goes on to narrate several cases in which untoward effects followed the administration of common remedies in the usual doses. He concludes by emphasizing his conviction that in the use and selection of a hypnotic, sleeplessness is perhaps the least important factor to be considered, although it may be the sole symptom of which complaint is made. The cause must be ascertained, together with any indications of idiosyncrasy. The co-existence of other diseases must influence the selection of the hypnotic, and even when, for the individual case, a suitable hypnotic has been found, risks of repeating moderate doses must be borne in mind. Generally the dose has to be gradually increased, especially when the cause has not been ascertained or satisfactorily dealt with, but with some drugs—e.g. sulphonal, trional, and tetronal—the danger appears to lie in the total quantity taken, even though each dose may have been small. But perhaps the greatest danger of all is incurred when the patient is given a prescription for a hypnotic, and this danger has certain analogies with the medicinal employment of alcohol. Many of us believe that at the height of fever, or in conditions of collapse, alcohol is often necessary, but it is never recommended to our patients for indefinite use, still less for increasing doses. Armed with a prescription for a hypnotic, patients commonly go on taking the drug long after the relief of the special circumstances for which it was prescribed, and the prescription may be used to facilitate the acquisition of large quantities of a dangerous drug obtained, perhaps, at several establishments in small amounts.

British Medical Journal, April 4, 1903.

The Surgical Treatment of Sciatica.—J. Crawford Renton exposes the nerve below the gluteus maximus, and separates the inflammatory adhesions around the nerve and up to the sciatic notch. No stretching of the nerve is employed. In perineuritis there is no pain when resting, but whenever the patient walks for a few minutes the pain commences. In some cases it takes six or eight weeks for improvement to take place, because the nerve has been dragged on by adhesions.

Head-drop Following Diphtheria.—Joseph Beard reports the case of a girl of six years upon whom he performed a tracheotomy. For about three weeks she improved. When it was noted that she had a nasal intonation of her voice and a little fluid returned through the nose when drinking. Her legs did not bear her body well, and she had trouble in raising her head and keeping it raised. The dropping of the head grew worse till she had no control over it. In about nine weeks from the onset of the illness, however, she had almost entirely recovered from the paralysis.

The Meaning of the Term "Neurasthenia" and the Etiology of the Disease.—P. C. Smith says that there is a condition not far removed from the etymological meaning of neurasthenia which stands in need of a name; it is an important factor in the etiology of the disease neurasthenia, and it is one of the most potent factors of unhappiness among men. This lesser condition may be described as neurasthenia minor, while the name neurasthenia major is given to the recognized disease. The former condition is hereditary, and is also congenital. It consists apparently of an inborn feebleness of nervous impulses, both centripetal and centrifugal. The conditions of neurasthenia minor and postnasal adenoids are very often associated. As to neurasthenia major, there appear to be two classes of cases from the pathogenetic point of view: (1) Cases arising from shock. (2) Cases due to the exacerbation of neurasthenia minor by depressing (or toxic) influences, such as worry and anxiety.

British Medical Journal, April 11, 1903.

Clinical Lecture on the Importance of Early Removal of Doubtful Tumors of the Breast.—J. Crawford Renton emphasizes the importance of early operation in any patient over thirty years of age. If the patient complains of a small hard lump in the breast, the sooner the lump is removed, along with the breast and the glands, in the majority of cases, the better it will be for the patient. A simple cyst may be dissected out and examined microscopically for malignancy, but when multiple cystic disease exists, the whole breast should be removed. The writer quotes a number of cases which come under the category of doubtful tumors of the breast, examination of which, after their removal, proved them to be cancerous.

Puerperal Hyperpyrexia of Malarial Origin.—Percy B. Spurgin reports this case: The patient had lived in India for some years prior to her marriage. The labor at the time of this report was most difficult, owing to contracted pelvis. The temperature for thirty-six hours afterward was normal, and the patient was doing well. But on the evening of the second day there was intense headache and dull aching in every limb. The temperature was 103° next day, it was the same in the afternoon, but had risen to 103.2° in the evening. There was itching of the skin all over the body. On the following day a rash developed. The diagnosis was tertian ague, and the chart bears it out.

On Recurrent Abortion, with Special Reference to that Form Due to Deficient Vitality of the Mother, or Both Parents, and Often Associated with Some History of Tuberculosis.—John W. Taylor states that of the rarer forms of recurrent abortion, a few are due to intraperitoneal adhesions, and especially to those associated with chronic appendicitis. Another very occasional cause is a deep laceration of the cervix. There is a definite group of cases of nearly equal importance to that belonging to syphilis, and the most distinguishing features which bind these cases together are: (1) Indications of a low vitality on the part of the mother or father, or both parents. (2) A "strumous" family history. (3) The remarkable result of an essentially "antistrumous" treatment when carried on for a long period of time or throughout the whole of the pregnancy.

Berliner klinische Wochenschrift, March 23, 1903.

Osmotic Pressure of Human Bile.—H. Strauss shows that the osmotic pressure of human life is practically the same as that of the blood. The bile was obtained from two persons who had biliary fistula, and the osmotic pressure was estimated on the basis of the freezing point These results are opposed to those recently reported by Messedaglia and Coletti, who found that human bile taken post-mortem shows a higher osmotic pressure than that of the blood—this is probably to be accounted for by the renal insufficiency which develops shortly before death. The administration of water has no influence upon the osmotic pressure of the bile, but when salt-solution (5 per cent.) is given the freezing point is lowered from two to three degrees centigrade.

French Journals.

A Case of Primary Epithelioma of the Uterine Tube.—Danel states that primary epithelioma of the Fallopian tube is a rare affection. The patient was forty-seven years old. Her trouble was diagnosed as uterine fibroma. Two years before, she was seized with pain in the lower pelvis associated with the rectum. It was thought that there was a purulent pocket which had pressed against the rectum. It opened spontaneously into the intestine at the end of a few days. The pain ceased and the patient thought she was well. In about five months the patient was suddenly seized with pain in the kidneys. An abundant white discharge also appeared. Examination was made, and the diagnosis of old perimetrosalpingitis was established. Operation was undertaken, supravaginal hysterectomy being performed. The uterus was the size of two fists. The wall was hypertrophied. All of the posterior surface was covered with adhesions. The adnexa were abnormal. The right tube was epitheliomatous. In a few months the patient returned with symptoms of intestinal obstruction. An artificial anus was made, but death soon occurred. The diagnosis of primary epithelioma of the Fallopian tube has probably never been made before operation.—*Journal des Sciences Medicales de Lille*, March 14, 1903.

Two Observations of Multiple Hæmatomas in the New-born.—Bouchacourt and Jeanin have observed these cases of new-born children who presented phenomena of infection not clearly understood, with jaundice, and in which were found, at autopsy, a series of hæmatomas. The first infant was a "bleeder," and probably syphilitic. He suffered from repeated umbilical hemorrhages, which could not be arrested by any treatment, even adrenalin. There were various hæmatomas and ecchymoses over places where there had been any pressure, whatever. Death rapidly supervened. The second child presented an eruption which looked like erysipelas, but which was not due to the streptococcus. At autopsy an enormous hæmatoma was discovered in the left psoas. Its origin was unknown, as the birth had been spontaneous and

normal. Although in the first case the infection was certainly of umbilical origin, this could not be affirmed of the second case.—*La Presse Médicale*, March 28, 1903.

Thoracic Traumatism and Pulmonary Tuberculosis.—Franchomme states that the development of pulmonary tuberculosis consecutive to traumatism of the thorax is considered possible by pathologists. However, the conditions of this evolution are not set forth in an explicit manner in classic works. The writer then reports a case: The patient suffered an industrial accident, by means of which the second, third, and fourth ribs on the left side were broken. The ribs were set. The hygienic surroundings were poor. In six weeks after the accident the patient seemed in very good condition. But shortly after this, in the tenth week, he began to cough; fever appeared, his appetite diminished, and he began to lose flesh. In spite of all precautions, pulmonary tuberculosis advanced, and he died five months after the accident. The defective hygienic conditions favored the development, in a soil prepared by the results of the accident, of the germs of this disease which are scattered everywhere.—*Journal des Sciences Médicales de Lille*, March 28, 1903.

A Case of Cerebral Rheumatism.—F. Vandeputte reports this interesting case. The patient was a man of thirty-nine years, who had an attack of rheumatism in the left knee, on December 13, 1902. There was nothing striking in the family history. The patient was a hard worker and an alcoholic. Salicylate of soda was prescribed. Nothing abnormal was noted in the urine. A slight murmur developed at the cardiac apex. A blister was applied over the precordial region. There was great prostration and much sweating. Drinks were ordered to be given in abundance. An eruption developed over the thorax and abdomen. The writer fearing cerebral complications, ordered the cold pack, but this was refused by the family. Insomnia persisted, accompanied by tranquil delirium and professional preoccupations. The temperature and pulse rose, and the patient became comatose, while from time to time there were convulsions localized to the inferior members. On December 24 the respiratory became difficult, the face cyanotic, and the patient died some hours later in hyperthermia. The writer asks if it was alcohol which had put the brain into a condition of least resistance.—*Le Nord Médical*, April 1, 1903.

The Nasal Origin of Iritis.—L. C. Bachand concludes that (1) The etiological causes of iritis are numerous, and iritis called idiopathic tends more and more to disappear from pathological records. (2) The infectious origin of iritis is demonstrated by the existence of numerous and indisputable facts. (3) The nasal origin is demonstrated: (*a*) By the absence of causes generally invoked in the production of iritis; (*b*) by the coincidence of the beginning of iritis with a nasal inflammatory attack; (*c*) by the influence of treatment or the rapid disappearance of ocular accidents coincident with the amelioration of the nasal affection. (4) The pathogenic study of this affection is represented by three theories: (*a*) The nervous theory, the vascular theory, and the infectious theory. It is the last, based on recent observations, that seems the best. (5) The symptoms of iritis of nasal origin are those of iritis in general. (6) The prognosis is good, excepting the old cases, in which pupillary occlusion necessitated surgical intervention. Treatment consists in allaying pain and avoiding synechiæ, and especially in treating the primary nasal affection.—*Le Bulletin Médical de Quebéc*, February, 1903

The American Journal of the Medical Sciences, Feb., 1903.

A Case of Multiple Melanotic Sarcoma Unsuccessfully Treated by X-Rays.—James P. Marsh urges *x*-ray therapeutists to have their work in large, rapid-growing sarcomata checked up by a frequent examination of the blood, especially as regards the leucocytosis. Although the *x*-ray seems to be of inestimable value in the ordinary slow-growing epitheliomata of the skin before glandular development has occurred, still the *x*-ray therapeutist should be willing to apply the same three-year rule to his work as does the general surgeon. Several times during this treatment of cases of recurrent cancer of the breast, the writer has felt that although the local condition has been much benefited, metastases in the internal organs occurred much more quickly than they used to do under the old methods of treatment. In the case reported, of multiple melanotic sarcoma, the writer had the question of leucocytosis investigated, and the blood examinations showed a steady fall in the number of leucocytes with each treatment. It seemed as if the *x*-ray treatment was having a direct detrimental effect, and, in the interest of the patient, it was discontinued

The Pathology of Labial and Nasal Herpes and of Herpes of the Body Occurring in Acute Croupous Pneumonia, and Their Relation to the So-called Herpes Zoster.—William Travis Howard concludes that: (1) Herpes zoster is a pathological condition, like pneumonia, for instance, with definite lesions of certain sensory ganglia sensory nerves, and the skin, capable of being excited by a variety of causes. It is probable that the primary ganglionic lesions are commonly due directly or indirectly to the soluble toxins of various microorganisms. The skin lesions may be on the head, neck, trunk, or extremities, corresponding to the Gasserian and posterior root ganglia affected. (2) Various forms can be distinguished: spontaneous or primary herpes: herpes occurring after certain definite toxic agents, as arsenic, etc.; herpes occurring in the course of certain acute infectious diseases, as pneumonia, cerebrospinal meningitis, and probably of malarial and typhoid fevers; herpes simplex, so-called. (3) As far as changes in the skin in herpes are concerned, they are illustrations of particular forms of necrosis and inflammatory reaction, and, as in similar lesions in other organs, can probably be excited in a variety of ways. (4) Herpes should be classified according to its relation to changes in the nervous system, and to this end every possible opportunity should be embraced for extending our knowledge in this direction.

Diseases of the Pancreas.—John B. Deaver states that the pancreas holds a relation to many important structures, and the severity of the symptoms when it is attacked by disease is undoubtedly due to this relation. Pancreatitis may be divided, clinically, into acute, subacute, and chronic. The acute form is characterized by the sudden onset of pain in the epigastrium, colicky, and accompanied by prostration and anxiety. Vomiting is an early symptom and is, as a rule, severe. There is a tender swelling in the epigastrium, tympanitic upon percussion. Constipation develops. Collapse may rapidly follow, with a distending and rigid abdomen, small, rapid pulse, irregular temperature, delirium, and death. In the less acute cases life may be prolonged for days, and recovery sometimes occurs. The diagnosis is difficult. Subacute pancreatitis will present the general symptoms of the more severe type, but in a lessened degree. Chronic indurative pancreatitis is probably a more common disease than the number of reported cases seems to show. The chronic form must be treated by abdominal section and cholecystostomy. Of the new growths occurring in the pancreas, carcinoma is the most frequent. Malignant disease of the pancreas is better left alone, or a palliative measure performed, such as cholecystostomy or cholecystenterostomy. The writer concludes his paper by a short summary of *x*-ray findings in pathological conditions of the pancreas, by M. I. Wilbert.

A Study of Some Cirrhoses of the Liver.—Beverley Robinson gives as the principle forms of cirrhosis: Atrophic, hypertrophic, and syphilitic. As to their pathology, in the hypertrophic, the fibrous tissue is finer, less formed, accompanied by a cellular growth, and runs along the smaller branches interstitially. In the atrophic form this fibrous tissue is coarser, better formed, shows greater tendency to contract upon and disorganize liver cells, extends along larger branches of the interstitial tree, and is not accompanied by cellular growth to the same degree at all. In syphilitic cirrhosis there are broad bands of fibrous tissue, which penetrate between the lobules and draw the liver down near the surface in such manner as to leave the puckered, scarred appearance, with bossy, prominent, irregular masses between, which are so characteristic. In atrophic cirrhosis the main distinguishing clinical feature is the evidence of marked portal obstruction. Abdominal effusion arises. Jaundice is a rare sign. The real duration of these cases is long. In the hypertrophic form ascites does not often occur, but jaundice is a marked and almost omnipresent symptom. Like to atrophic cirrhosis, hæmatemesis is not infrequent. As to clinical symptoms, syphilitic cirrhosis resembles one of these two forms. There may be jaundice and no ascites, or there may be both ascites and jaundice. Or, neither sign may be present. Despite the fact that it is affirmed that jaundice does not occur in atrophic cirrhosis, it would seem as though we may and do have jaundice in all forms of cirrhosis. Jaundice occurs earlier in the hypertrophic form than in the atrophic. The prognosis of hepatic cirrhosis has usually been most gloomy. To-day we are more encouraged, and regard certain cases very hopefully. The first indication of treatment is from the point of view of arresting growth of fibrous tissue in the liver, and to the preservation of the remaining healthy liver cells. This is accomplished, if at all, when alcohol has been an etiological factor, by the abandonment of its use.

Society Reports.

THE PRACTITIONERS' SOCIETY.

One Hundred and Seventy-eighth Regular Meeting, Held on Friday, February 6, 1903.

Limitations of Diagnosis and Results.—By Dr. EDWARD G. JANEWAY (vide page 641).

Dr. BEVERLEY ROBINSON said that every practitioner of medicine could doubtless recall instances in which he had been mistaken in his diagnosis, and there was comfort in the fact that such mistakes could not always be avoided. He agreed with Dr. Janeway that there were certain limitations of diagnosis, which could be pretty distinctly drawn. In doubtful cases, when the probabilities pointed in a certain direction, he thought it better to make a provisional diagnosis, even if it subsequently proved to be wrong, rather than to make a "snap" diagnosis and be correct.

Dr. ROBERT ABBE said that the subject of Dr. Janeway's paper appealed to both the physician and the surgeon, and in the diagnosis of doubtful cases he was more and more inclined every day to take the advice of the late Dr. Geo. A. Peters, and "let it simmer." The trend of the times, however, was to make a diagnosis as quickly as possible, and get results promptly. In certain surgical conditions, particularly in tuberculous lesions, a positive diagnosis was often very essential. The speaker inquired whether the injection of tuberculin for diagnostic purposes, would be safe and reliable and justified as a routine measure—for example, in tuberculous peritonitis? There were certain other surgical conditions in which a positive diagnosis could not be made promptly, particularly in abdominal cases. For the purpose of clearing up such a case, he thought an exploratory operation was more justifiable nowadays than formerly, providing the operator was willing to stop short at a certain point, and not do more than he had planned to do nor the patient was willing to have done.

Dr. ROBERT F. WEIR said that Dr. Janeway's paper offered many opportunities for discussion. The possible difficulty of recognizing tuberculous lesions had been suggested by Dr. Abbe, and the following case, which the speaker saw in consultation a few days ago, had some bearing on that point. The case was one of orchitis, the testis being swollen and very painful. The physician in charge had made an injection of tuberculin, which produced no reaction, and this had led him to suspect that the case was one of sarcoma. Dr. Weir, however, still believed that the lesion was tuberculous, and a second injection of tuberculin was followed by a satisfactory reaction. At a subsequent operation, the epididymis was found to be tuberculous. In doubtful lesions, especially of the tongue, when the diagnosis rested between epithelioma and syphilis, the results of a test treatment with potassium iodide were not always to be relied upon, because cancers of the tongue often improved temporarily under the use of large doses of that drug. But unless this treatment was followed by a decided and continuous improvement, too much importance should not be attached to the result of it. In such cases a more prompt diagnosis is made by the removal and examination of a section of the growth. In reference to the mistake made by a prominent Western surgeon, alluded to by Dr. Janeway, who had operated for the removal of a tooth-plate which was supposed to be obstructing the œsophagus, Dr. Weir said there was much justification for the error. It has been made apparent in the published report of this case that during the desperate efforts that were made to remove this supposed obstruction, before the surgeon saw the patient, the hyoid bone was grasped by an instrument and the tissues of the lower pharynx were considerably lacerated, resulting in œdema, which spread to the larynx, producing such severe obstruction to respiration that a tracheotomy became necessary. This clouded the instrumental examination of the œsophagus. The *x*-ray shadow, which was supposed to be the foreign body, was produced by a calcified plate of the aorta.

Dr. GEORGE L. PEABODY reported the following case as an example of a mistaken diagnosis: The patient was a man who was unable to speak English, and it was impossible to get his previous history. He had a high temperature, several chills with sweating, and on the skin there were a few perfectly distinct, punctate hemorrhagic spots. A blood culture was made, and the pathologist reported that streptococci were present. The case was thereupon regarded as one of clinical sepsis and a bad prognosis was given. About ten days later the patient had a copious hemorrhage from the bowel, and subsequent observation showed the case to be one of typhoid fever, from which the patient made an uneventful convalescence. The only explanation Dr. Peabody could offer for the presence of streptococci in the blood was the supposition that the pathologist had confused the blood with that of another patient. As to tuberculin, Dr. Peabody said he did not hesitate to use it for diagnostic purposes. Occasionally, harmful results had been reported from its use, but these occurred so rarely that he considered it perfectly proper to resort to it.

The speaker thought the numerous laboratory aids now availed of in diagnosis were likely to make the rising generation of physicians more careless observers, and lead them to place less reliance upon their own skill and experience. There were many able young physicians to-day who would not make the diagnosis of typhoid fever without the Widal reaction, in spite of the fact that the latter often could not be obtained until the end of the second week. Too much reliance was also placed upon the presence or absence of tubercle bacilli in the sputum in cases of suspected pulmonary tuberculosis to the neglect of history, symptoms, and physical signs. The speaker mentioned a case of fatal pulmonary tuberculosis in which the tubercle bacilli were never found, and only on one occasion during several weeks of observation could sufficient purulent sputum be obtained for a satisfactory examination. All the other symptoms of the disease, however, were present.

Dr. Peabody agreed with Dr. Weir that potassium iodide would temporarily relieve the symptoms of a non-syphilitic tongue lesion, and he recalled a case of cerebral tumor, which subsequently proved to be a sarcoma, in which the symptoms were markedly improved for a time by large doses of the iodide. He explained this fact by the diuretic action of the drug and its effect upon the heart, which tended to relieve local congestion and pressure in the neighborhood of the lesion. It had no permanent good effect, excepting in syphilitic lesions, but one might easily be misled by its transitory influence.

In some cases of syphilis of the liver, after bands of connective tissue were formed and pressed upon important branches of the portal vein, with the subsequent development of ascites, no amount of anti-syphilitic treatment would remove those bands. If the treatment were given sufficiently early in the course of the disease, it would relieve the pain and fever and the general hepatic symptoms, but after the formation of cicatricial bands, it would have very little effect. Such a case had recently come under his observation. He mentioned this as illustration of a syphilitic lesion which would not yield to specific treatment, and in the case of which, treatment would not assist in making the diagnosis.

Dr. HERMANN M. BIGGS said the difficulties in recognizing smallpox were often very great, and sometimes even insurmountable, especially in the country. Last December he went to a town in Connecticut to inspect a number of doubtful cases which had given rise to much uncertainty. The first case had been seen several months before, and had been pronounced impetigo. Subsequent

cases were regarded as chickenpox. During Dr. Biggs' visit he found thirty cases of smallpox, all of them, with one exception, of an exceedingly mild type, most of the patients being up and about. The exceptional case was one of confluent smallpox. In order to illustrate the difficulties surrounding the diagnosis of smallpox in certain instances, the speaker mentioned the following case: A patient with an eruption of doubtful character was sent to the Reception Hospital and examined by all of the diagnosticians of the Board of Health—men who had been seeing smallpox for ten years and more—and the consensus of opinion was that the case was not one of smallpox. A year or two ago the discovery was made that it was possible to differentiate between smallpox and chickenpox by inoculating monkeys, as they were very susceptible to the former disease. In the doubtful case referred to above, which had not been regarded as smallpox by the diagnosticians of the Health Board, inoculation upon a monkey produced typical smallpox pustules. Dr. Biggs said the inoculation test with monkeys was a very useful one in the very mild cas s of smallpox, which have occurred in large numbers throughout the country during the past few years. Such a doubtful case could be kept under observation for four or five days, and during that time the inoculation of a monkey would determine the true character of the disease. The speaker said that three or four years ago he had a conversation with Koch in regard to the use of tuberculin for diagnostic purposes, and Koch had informed him that every patient who was admitted to the Institute for Infectious Diseases in Berlin, who did not show well-defined symptoms of tuberculosis was given tuberculin in order to exclude the presence of that disease. In the well-defined cases of tuberculosis the test was omitted, but patients who were suffering from any other form of infectious disease were injected with tuberculin in order to exclude tuberculosis. At that time it had been administered to over 5,000 patients as a routine measure, and Koch said he had never seen any unfortunate results follow its use. The first injection was limited to one milligram, and if, after three or four days had elapsed, no reaction followed, a second injection of two and one-half milligrams was given, and if this was followed by no reaction after three days, a third injection of five milligrams was given. If there was any reaction at all, after any one of the injections, then a second dose of the same amount was administered. A slight reaction after one dose was usually followed by a more severe reaction after a second similar dose. Koch stated that he was never satisfied with the result of a single injection, and that the dose varied in different individuals. The observation of a single case often occupied two weeks.

Dr. Charles Stedman Bull said that cases of optic neuritis like those referred to by Dr. Janeway were not particularly rare. He could recall eight cases of optic neuritis, with hemorrhages and marked disturbance of vision, occurring at the age of puberty without any apparent cause. He had under his care at the present time a girl of seventeen who had never menstruated, and who recently developed a double papillitis, with hemorrhages strewn all over the retina. There was apparently no other symptom, either subjective or objective, anywhere in her body. He had put the case down as one of papillitis at the menstrual epoch, but with no menstruation. All of these patients, Dr. Bull said, regained a certain amount of useful vision, and in two of his eight cases normal vision was regained after a varying length of time. The actual loss of vision was more dependent upon a general retinal œdema than upon the hemorrhages or the swelling of the optic disk.

Dr. Abbe inquired whether a single tuberculous nodule in the body, without general tuberculosis, would give a reaction to the tuberculin test? He recalled the case of a small mammary tumor which, after its removal, proved to be tuberculous, although its true character had not been suspected before. In order to learn whether any tuberculous tissue was left in the system, an injection of tuberculin was given. This was followed by no reaction, and the patient had remained well since the operation, a period of over four years.

Dr. Janeway, in closing, said that one difficulty with the tuberculin test was that it did not tell you where the lesion was located. Councilman of Boston obtained a reaction in a syphilitic lesion of the lung. Dr. Janeway said he could not agree with the statement made by Koch that the use of the tuberculin was practically harmless, or, at any rate, that he had never seen a single bad result follow the injections. Personally, he would not resort to it unless he considered it absolutely essential. He understood that Koch himself had changed his method in regard to the use of tuberculin, and now practically followed the same practice as Dr. Trudeau, and gave it only in the afebrile cases—not in the febrile cases. Dr. Janeway said he had seen four cases of optic neuritis, three in girls and one in a boy, which developed at the age of puberty, and for which absolutely no cause could be discovered. There were no other symptoms anywhere in the body. In former years, the speaker said, such an optic neuritis would, no doubt, have been regarded as an evidence of brain tumor.

Successful Removal of a Piece of Steel from the Interior of the Eye.—Dr. Charles Stedman Bull reported the case of a man, who, as the result of a machinery explosion, was struck in the eye by a flying fragment of steel. It perforated the cornea, iris and lens, and entered the vitreous body, which became filled with blood. Three hours after the accident, when Dr. Bull first saw the patient, it was decided to make an attempt to extract the foreign body by means of the great Haab magnet. At a distance of one and three-quarter inches the action of the magnet produced such a violent disturbance within the eye that it seemed as though the latter would be pulled from its socket. This left no doubt as to the location and nature of the foreign body. The wound in the cornea was thereupon enlarged, and when the eye was then brought into almost actual contact with the magnet, a piece of steel, about four millimeters long, and about three and one-half millimeters wide was drawn out through the original hole in the lens, iris and cornea, and became adherent to the pole of the magnet. An ophthalmoscopic examination made subsequent to the removal of the foreign body showed a hemorrhage of the vitreous. After a period of ten days' treatment the patient was discharged from the infirmary with the hole in the cornea and iris partially closed, and his vision was about two-thirds normal. There was no further cloudiness of the lens, in spite of its having been perforated. Dr. Bull said the case reported was the most favorable one of the kind he had ever observed. The future of the case would be interesting. In many instances in which a foreign body had entered the posterior part of the eye, the eyeball was ultimately destroyed, even after removal of the foreign body.

The Changes in the Uterus in the Course of Acute Infectious Diseases.—Stravoskiadis, after an exhaustive analysis of cases, comes to the conclusion that infectious diseases are frequently complicated by an acute inflammation of the endometrium, which is often hemorrhagic, but may be of a different nature and vary in degree. This inflammation is usually caused by specific organisms which correspond to those producing the original infection; though when complications supervene it may be their organisms which excite the endometritis. This infection of the uterus is effected by way of the blood current, and is predisposed to by pregnancy or the puerperium. The abortions and premature labors occurring in the course of the acute infectious diseases are frequently induced by such an endometritis of hæmatogenous origin. —*Monatsschrift für Geburtshülfe und Gynäkologie.*

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held April 16, 1903.

VIRGIL P. GIBNEY, M. D., VICE-PRESIDENT, IN THE CHAIR.

THIS meeting was in charge of the Section on Laryngology and Rhinology.

The Relation of the Diseases of the Upper-air Passages to the Diseases of the Gastrointestinal Tract.—Dr. LEWIS A. COFFIN presented this paper. He said that these diseases were of special interest because of their almost universality. He had been struck with the large number of patients complaining solely of the symptoms of chronic nasopharyngitis, or postnasal catarrh. The disease *per se* was a local one, and might or might not be associated with disease of the other parts of the upper-air passages. Considerable modification of the voice might occur, and complaint was sometimes made of affection of the middle ear. The stoppage of the nostril lying next the pillow at night was probably dependent upon enlargement and hyperplasia of the posterior ends of the inferior turbinate bones. Where the condition was of very long standing there was apt to be atrophy of the mucous membrane. The pathology was the pathology of a cirrhotic membrane. Among the various causes of postnasal catarrh were: (1) direct irritation from the inspiration of impure air; (2) extension of the catarrhal inflammation from the mucous membrane lining the nasal cavities; (3) structural deformity of the nose; (4) irritation from the drainage of secretions from diseased accessory sinuses of the nose; (5) reflex action from disordered digestion; (6) lithæmia, and (7) direct irritation from the gases and products of fermentation from a disordered stomach. The mucous membrane of the anterior nares of such a patient might or might not be diseased, and this fact led one to look for the cause outside of the respired air. Children, although seldom presenting great structural deformity of the nose, were quite as frequently affected as adults. Examination revealed a thoroughly diseased condition of the inferior meatus, whereas no such change was observed in the middle or superior meatus. The author believed the chief cause was to be found in the escape of gases from a disordered stomach and the consequent direct irritation of the mucous membrane. Dyspeptic children were constantly throwing up food and the irritating products of disordered digestion into the pharynx. The pharynx of such a child presented an appearance very similar to the granular condition observed in adults. The speaker said that quite recently he had predicted the development of an attack of otitis media in an infant whom it had been found very difficult to feed, and who was constantly vomiting. Within a week or two the prediction was fulfilled by the occurrence of an otitis media first on one side and then on the other, evidently the result of the irritation produced by the vomited matter. The irritating quality of certain subacid contents of the stomach was almost as great as that found in persons suffering from hyperacidity. Many of those suffering from acid dyspepsia had nasopharyngeal catarrh and were not aware of the existence of dyspepsia, but careful inquiry would usually reveal the presence of symptoms of gastric hyperacidity. He believed the enlargement of the posterior ends of the turbinates was often responsible for the catarrhal and empyemic conditions found in the anterior nares and various sinuses, as it acted by preventing drainage, thus favoring bacterial growth and infection. With the kind coöperation of Dr. W. D. Roberts he had succeeded in securing a careful examination of the stomach in fifteen children with adenoids and in thirty adults showing postnasal catarrh. Ten of the children and twenty-four of the adults presented more or less disorder of the stomach. Among the adults, twelve suffered from chronic gastric catarrh.

Some Relations between Diseases of the Nose and Throat and Those of the Thoracic Cavity.—Dr C. G. COAKLEY was the author of this paper. He said that, in order properly to appreciate the influence that the upper respiratory tract had upon the lower one must recall the fact that the function of the upper portion was to warm, moisten, and filter the inspired air. By the time the air had reached the nasopharynx it was completely saturated with moisture. The filtration of the air was accomplished partly by the hairs at the nostrils and partly by the sticky mucus secreted by the glands of the nose. Mouth breathing, if persisted in, was certainly most injurious. Although very vascular, the mouth had no cavernous tissue by which its blood supply could be so nicely regulated as in the nose. In cold weather one noticed the cold sensation when breathing through the mouth, and the absence of this sensation when air of the same temperature was breathed through the nose. The dust particles were not so readily entrapped in the mouth because the cavity was large. One of the commonest causes of mouth breathing in early life was enlargement of the tonsils and the associated condition, hypertrophy of the adenoids of the pharynx. In cases of anæmia, owing to the insufficient blood supply, the air was not sufficiently warmed, and the result on the upper-air passages was the same as already considered. Here local treatment was of no avail; constitutional treatment was called for. In the treatment of asthma it was most important to search carefully for special sources of irritation, whether they were located in the upper air passages or in the digestive system. In cases of chronic asthma it was highly probable that the nerve endings had become so sensitive that the asthma would continue even after removing the original sources of disturbance. Many practitioners were of the opinion that polypi and asthma were intimately associated, yet in his own records only about 15 per cent. of the patients showing polypi suffered also from asthma. It was not uncommon for nasal operations to be followed by relief from asthma for a period of several months, and then the disease would return as before. With regard to diseases of the lower respiratory tract giving rise to disease of the upper-air passages, the speaker said that cough should receive more attention. Coughing, if long, paroxysmal and severe, gave rise to hoarseness. Paralysis of one or the other vocal cord was sometimes seen. The left recurrent laryngeal nerve might be involved in a tuberculous deposit. Lesions of the heart frequently caused pathological changes in the throat which were readily recognized. The treatment in such a case should be directed first and foremost to the cardiac condition. The veins along the walls of the pharynx and the root of the tongue were very frequently enlarged in connection with cardiac lesions. Paralyses of the left vocal cord due to aneurysm of the aorta were common enough. In such cases the *x*-ray was occasionally of great service in detecting the source of the trouble.

Dr. MAX EINHORN objected to the position taken by Dr. Coffin with regard to the relation of disorders of the stomach to nasopharyngeal catarrh because eructations of irritative gases, such as sulphuretted hydrogen, were quite exceptional, occurring only in cases of obstruction of the outlet of the stomach. In the majority of cases of belching up of gas these eructations were totally unnecessary and were largely a matter of habit. Moreover, these eructations consisted chiefly of air. Again, his own experience showed that many patients, suffering from severe and long standing disorder of the stomach, the result of organic lesions and associated with eructations of gases, were wholly free from nasopharyngeal catarrh. In few cases disorder of the stomach resulted from disease of the nasopharynx, as, for example, in cases in which there was frequent swallowing of mucus. He had known transient attacks of acute diarrhœa to result from the swallowing of large quantities of this acrid mucus.

Dr. D. BRYSON DELAVAN said that he had been interested

in this subject for many years. Early in his experience with throat diseases he had noted that many cases of dry pharyngitis were associated with constipation, and that by curing the latter and applying stimulating applications to the throat, recovery ensued. He had not found it very often necessary to treat surgically the diseased lingual tonsil, because this condition was usually very amenable to treatment directed toward improving digestion. It was very common to find hypertrophy of the adenoid tissue of the pharynx in dyspeptic children, and, he thought, there could be no doubt that the products of defective digestion tended directly toward adenoid hypertrophy. Many cases of hyperæsthesia of the pharynx were relieved by the cure of the associated indigestion. While he believed all the conditions mentioned by him were dependent upon indigestion, one should not go too far in ascribing to this cause the many affections of the upper-air passages. He was of the opinion that paralysis of the vocal cord due to pleuritic adhesion must be excessively rare, and that many cases reported as having this etiology were really examples of ankylosis of the crico-arytenoid joint.

Dr. George R. Lockwood said that he recognized that there was a close connection between disease of the stomach and of the upper-air passages, yet on going over his records with the object of separating and classifying the cases it seemed almost impossible to make a satisfactory analysis. The cases giving a gouty history were not as numerous as he had been led to believe from a study of the literature. He had been astounded to find so many confirmed alcoholics with good gastric digestion and a normal condition of the throat. The morning retching of alcoholics, together with the irritation of the throat produced by the alcohol, must necessarily be powerful factors in the production of pharyngitis. Another group of cases having disease of the throat was that in which the individuals were addicted to over-eating and refrained from taking sufficient exercise. Cases in which the stomach and intestine were atonic, especially the colon, often exhibited a chronic congestion of the pharynx, probably as a result of toxæmia, for, in these cases the urine was loaded with indican and the patients suffered from congestive headaches. A third class comprised cases of hyperacidity, especially those associated with atrophy. In these cases, more frequently than in any others of acute gastric affection, there was apt to be pharyngitis, and they were also prone to develop areas of hyperæsthesia at the base of the tongue. He did not believe that the eructations of gas were etiological factors, because in most instances the gases eructated were atmospheric air and carbon dioxide. The patients suffering from hyperacidity were always troubled with an excessive secretion of saliva. These were the persons who were always salivated on passing the stomach tube. He was inclined to think that this free secretion of saliva was an effort of nature to dilute the acid secretion.

Dr. Beverley Robinson said that it was evident from this discussion that there must be a close and undoubted connection between throat affections and the state of the digestive tract. He had long deplored the strong surgical tendencies in laryngology and rhinology, and hence these papers and this discussion were reassuring as pointing to a better understanding and a closer association between this specialty and general medicine. Twenty-one years ago he had given to the profession a paper on impaired cardiac action as a cause of certain affections of the throat, and was surprised to find that after the lapse of so many years his views on this point had undergone but little change. In this connection he desired to say that very marked relief could be given in certain rather acute congestive conditions of the nose and throat by the administration of carbonate of ammonia and small doses of digitalis and strychnia.

Dr. Emil Mayer spoke of the importance of relieving reflex coughs those coughs occurring without secretion and without cessation, and aptly termed "useless coughs." It was not uncommon to find that the removal of some small and possibly hitherto unnoticed abnormality would promptly and permanently relieve a reflex cough of several years' standing. The speaker then spoke of the remarkably interesting and important experiments of Professor Dunbar on the relation of certain pollen to hay fever, and expressed the belief that it was reasonable to hope that in the near future one would see the effective treatment of hay fever by an antitoxin.

Dr. Charles E. Quimby thought there was no fixed connection between gastric disease and the throat and gastric disease and almost any other part of the body; it was only a question of the point of susceptibility in the individual.

Dr. Walter F. Chappell said he was not disposed to accept unconditionally Dr. Coffin's theory about irritation resulting from the eructation of gases being the cause of postnasal catarrh. He had seen more than one case of spasm of the larynx result from the excessive secretion of saliva following the eating of candy, particularly chocolate.

Dr. Coffin, in closing the discussion, said that those who had taken part in the debate had overlooked the fact that when he spoke of the eructation of gases he also mentioned that associated with this was the regurgitation of a most irritating fluid from the stomach. He did not remember a single case in which the patient had stated that the treatment of the throat had made the stomach well, but he could recall scores of cases in which appropriate treatment of the stomach had caused a prompt disappearance of the symptoms of the throat affection, although the local appearance might not yet appear to be quite normal.

SECTION ON SURGERY.

Stated Meeting, Held April 13, 1903.

Robert T. Morris, M.D., Chairman.

Observations on Retraction and Retractors in Abdominal Surgery; Demonstration of an Automatic Cœliotomy Retractor.—Dr. A. Sturmdorf read this paper. He said that the defects of ordinary retractors were made evident in prolonged abdominal sections which were rendered difficult by extensive adhesions. The edges of the wound were apt to be bruised and devitalized by the retractors ordinarily employed, and he was disposed to think that the late gaping of cœliotomy wounds recently reported might be explained in this way. To obtain a maximum of distension with a minimum of force the blades of retractors should be shaped as to exert their pressure upon the center. The shape of the retracting blade should conform to the line of the distended, and not the relaxed, wound. To accomplish this he made use of a retractor blade fitting the wound in the shape of an ellipse. In addition to this he used an automatic device for retaining the instrument in position. The retractor blade was modified from Fritsch and the self-retaining attachment from Kelly. The parts of the instrument were detachable for sterilization.

Dr. H. Lilienthal said that there was certainly room for a good automatic retractor, and while he did not believe this instrument would actually take the place of good hand retraction, still it should prove very useful.

Dr. M. S. Kakels said that he was familiar with the operation of this instrument, and had been surprised at the large field exposed for operation and the little damage done the tissues.

Dr. Robert T. Morris said that he had not given much consideration to the question of the amount of damage done to the edges of the wound by retractors. Personally he almost never used a retractor in abdominal work, and hence that would not explain his reported

case, in which there was late gaping of the abdominal wound.

The Relation of Cholelithiasis to Acute Pancreatitis with a Report of a Case—Dr. Joseph Wiener read this paper. He said that it was only in recent years that pancreatitis had been given the attention which it warranted. The brilliant paper of Fitz in 1889 had done much toward directing renewed attention to pancreatitis. Disease of the pancreas was often found associated with disease of the biliary system. When the duct of Wirsung was obstructed fat necrosis resulted, *i. e.* a splitting up of the fat into its component parts, fatty acid and glycerin. Besides fat necrosis, the signs of pancreatic obstruction were the presence of fat and undigested muscle fibers in the stools and glycosuria. The latter only resulted when the islands of Langerhans were involved, while fat in the urine was decidedly rare. A moderate inflammation in the head of the pancreas might cause that organ to enlarge sufficiently to obstruct the flow of both bile and pancreatic fluid into the duodenum. Infection of the gall-bladder and ducts often occurred without the presence of stone. Generally, the symptoms of acute pancreatitis at the onset were those of peritonitis in the epigastric and hypochondriac regions. According to Deaver, there was usually colicky pain in the epigastrium with prostration and anxiety, while vomiting was apt to be an early symptom. The pain was usually agonizing in character, differing in this respect from the pain in cholecystitis. In many cases tenderness and swelling were either very slightly marked or entirely absent. In twenty-six of the thirty-two cases collected by Opie there was fat necrosis. Dr. Wiener then reported his own case. The patient was a married woman of forty-one years who had been free from previous intraabdominal disease and had been in good health up to January 28, 1903. At that time she experienced sudden and agonizing pain in the epigastrium. The attending physician, Dr. Davidson, was disposed to make a diagnosis of appendicitis. When first seen by Dr. Wiener on January 30 there was a pulse of 120 and a temperature of 102° F., with rigidity of the upper half of the rectus muscle. Exploratory incision was advised and done. The appendix was long and tightly bound down by old adhesions. It was removed. The omentum was thickly studded with small, irregular opaque white patches. There was a large stone in the cystic duct, which was milked back into the gall-bladder and cholecystectomy rapidly performed. No other stones were found. The head of the pancreas felt distinctly hard, but was not thought to be enlarged. The operation lasted one hour, and free hypodermic stimulation had to be resorted to. The gall-bladder was found to be enlarged and elongated, and its walls were dark and thickened. The omentum was found to be the seat of typical fat necrosis. Albumin and many casts were present in the urine. Gas and ether were the anæsthetics employed. On February 15 there were dulness and bronchial voice over both lungs. For some time after the operation the patient suffered from pulmonary consolidation, but this cleared up eventually, and on the eighteenth day after the operation she was allowed up. Four days later, the wound having completely healed, she left the hospital. These cases constituted another potent argument for early operation in cholelithiasis as well as for acute pancreatitis. In this case it was true a correct diagnosis was not made, but the successful issue was due to the early resort to exploratory operation.

Dr. Davidson, who was the attending physician in the case just reported, said that no doubt these cases were much more frequent than was supposed. There was no reason why septic organisms should not enter the pancreatic duct just as they did into the cystic duct. Four cases had been reported by Opie in which persistent vomiting had caused the affection. Four varieties of acute pancreatitis were usually described, viz.: (1) The ordinary; (2) the hemorrhagic; (3) the suppurative, and (4) the gangrenous. It was only in the simple form that there was much prospect of relief. In the case reported the agonizing nature of the pain seemed to be the most characteristic symptom. This pain was localized in the epigastrium and not over the liver or in the right iliac fossa. Palpation usually afforded no information. The fæces should always be examined, and if much muscle fiber or free fat were present, this finding would go a long way toward establishing the diagnosis of acute pancreatitis.

Dr. Sturmdorf said that cases in which the cystic duct alone was involved were not usually the ones in which acute pancreatitis was commonly found; hence the case appeared to be unusual, and in need of further elucidation.

Dr. Lilienthal believed that it was practically impossible to make a diagnosis of the more acute forms of acute pancreatitis. He was of the opinion that the disease was not always a surgical one by any means, occasional instances of recovery without operation being on record. Chronic pancreatitis was more important from the standpoint of the diagnostician, for such cases demanded operation, and indeed were commonly operated upon under an erroneous diagnosis. In the chronic form every effort should be made to make an accurate diagnosis. Here, a cholecystotomy could be done, thus draining the gall-bladder and relieving the pancreas to a certain extent, and massage could be applied to the pancreas. There were numerous cases on record in which recovery had followed operation in suppurative pancreatitis. He had had several cases in which there were occlusion of the common duct and deep jaundice in connection with pancreatic tumor; he had also found a stone in a common duct and none in the gall-bladder, the latter being atrophied and very small.

Dr. C. A. Elsberg said that a large number of experiments had been carried on to determine the cause of fat necrosis, and it had been found that only exceptionally did fat necrosis result from artificial obstruction of the duct of Wirsung. Normally the pancreatic and common bile ducts opened by a common mouth, but close examination would show the presence of a distinct septum, thus giving two separate openings.

Dr. A. V. Moschcowitz said that he had seen two cases of acute hemorrhagic pancreatitis without operation and without fat necrosis. In both cases the autopsy revealed extensive retroperitoneal hemorrhages. Acute pancreatitis was evidently especially common in alcoholic subjects. No mention had been made in the discussion of a peculiar cyanosis of the abdomen that was observed in some of these cases.

Dr. Charles H. Peck said that last summer he operated upon an obscure case presenting certain symptoms suggestive of an acute cholecystitis. There was considerable fever associated with tenderness and rigidity on the right side. An exploratory operation revealed thickening of the gall-bladder and some adhesions. The region of the appendix was normal. There was no suppuration of the gall-bladder and exploration of the ducts revealed no stones. The gall-bladder was drained and the patient recovered after a time, the temperature falling slowly.

Dr. Churchill Carmalt said that the septum between the two ducts at their openings was not so common as some seemed to think, being met with about once in four subjects in the dissecting-room of the College of Physicians and Surgeons, Columbia University. Experiment had shown that most of the so-called symptoms of pancreatitis could arise from mere traumatism of the pancreas without the ducts being affected at all.

Dr. R. T. Morris said that he had had a case in which a gallstone ruptured near the ampulla and escaped. The resulting hemorrhage apparently dissected away the

peritoneum in such a way as to entirely decapsulate the pancreas; at any rate, when he operated it was found converted into a slough. The patient made a good recovery, but developed a glycosuria. He thought the agonizing pain was due to the proximity of the pancreas to the semilunar ganglia. It was probable that obstruction plus sepsis accounted for the large proportion of the cases in which fat necrosis was associated with obstruction of the common bile duct.

Dr. WIENER closed the discussion. He expressed the opinion that acute pancreatitis was quite a common disease, as might be expected by reasoning from analogy. In quite a number of the reported cases the pain was not in the epigastrium; moreover, in about 30 per cent. of cases of appendicitis the pain was epigastric during the first day or two, and in many cases of cholecystitis the pain was also in this region, so that epigastric pain could not be considered at all characteristic. The swelling of the common bile duct could just as well obstruct the duct of Wirsung as could a stone. It was quite probable that a large number of cases of acute pancreatitis recovered without operation, and, indeed, without recognition.

Mesenteric Cyst.—Dr. ROBERT T. MORRIS presented this specimen. Although possessing a well-marked capsule, it was found to be a papillomatous sarcoma, probably derived from a lymph grand.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending April 18, 1903:

	Cases.	Deaths.
Measles	298	1
Diphtheria and croup	345	51
Scarlet fever	272	28
Smallpox	2	1
Varicella	83	..
Tuberculosis	318	183
Typhoid fever	64	5
Cerebrospinal meningitis	..	..

This Germ-infested Globe.—A German scientist announces that 12,000,000 bacteria inhabit the skins of half a pound of cherries. Currants come next with 11,000,000 to every half pound and grapes next with 8,000,000. Clean all fruit before eating, says this bacteriologist; peel or wash it. Evidently in the midst of life we are in death. How anybody manages to keep alive is a mystery. One would suppose that the planet would long ago have become a vast graveyard, in which about, in reel and rout, bacteria might dance in undisturbed supremacy.

When you sit down to dinner swarms of germs attend you. Is the drinking water boiled? A paltry five or ten minutes will not do. There are bacteria that will not succumb in less than an hour or two of vigorous boiling. And then who knows whether a few million germs failed to be washed out of the tumbler. Be careful of the milk. Salt the meat with disinfectants and butter the bread with germicide. By the time the tomatoes are peeled to get rid of the surface bacteria, and seeded to avoid the danger of appendicitis, there is not much left, to be sure, but then what remains is at least healthful. It is no small job to remove the skin from a currant in accordance with the latest recommendations of science. But much better work half a day over a saucerful than be dead the rest of one's life.

Mince and pumpkin pie by all means should be sterilized before eating. Boil carefully for an hour the day before serving, set away in a hermetically-sealed glass case and pasteurize on the day of the dinner. But the danger in food is only one of the variety of perils which modern science has revealed. Everybody knows that kissing is insanitary and that handshaking is frowned upon. Billions of noxious creatures lurk in the dust of the most carefully-kept house. The hygienic home should be constructed with curves to avoid corners. It must have no curtains, no rugs or carpets, no pictures. Have the housemaid scrub it every day with carbolic acid.—*Kansas City Star.*

The Use of Steam in Gynecology and General Surgery.—Steam as a disinfectant and hæmostatic, suggested about fifteen years ago by Prof. B. L. Suegeron, is, according to M. F. Kozleuko, gradually coming into general use in gynecology and surgery. In gynecology it is used in cases of persistent metrorrhagia and leucorrhœa occurring about the menopause. Such affections during the relaxed condition of the uterus at the menopause may be so persistent as to defy all treatment and make an hysterectomy imperative, while, at the same time, in the majority of such cases the general condition of the patients, weakened from prolonged hemorrhages and leucorrhœa, the condition of their hearts and kidneys, their atheromous arteries—all these conditions contraindicate a radical operation. In such cases the application of steam for the removal of the entire diseased mucous membrane, being painless, and obviating the use of narcotics, appears almost as a life-saving means, the more so, since after the application of steam, coalescence of the uterine walls occurs, with complete cessation of the metrorrhagia, leucorrhœa, and the menstrual discharge. In surgery steam may be used in operations on the liver as an hæmostatic without the addition of any other means. The parenchymatous hemorrhage from the wounds of the liver is stopped with the steam saw; the arterial hemorrhage—with the saturated steam passing through a tube applied obliquely to the wall of the artery. This is the more valuable to us, since up to the present time we have no absolutely safe hæmostatics in operations of parenchymatous organs. Lately B. F. Aregerov has used the steam saw in an operation of the kidney in pyelitis, without the loss of a single drop of blood. Steam may also be used in diseases of the eye and ear, nose and throat. —*Russkii Vratch.*

Old Methods of Treatment Which Are Not Necessarily Obsolete.—H. W. Syers decries the use of so-called hypnotics and an ipyretics in the treatment of fevers to the neglect of opium. This he considers the most reliable and the safest and most satisfactory drug in these cases. The antiseptic treatment of the alimentary canal in typhoid fever he believes to be as hopeless a proceeding as to undertake to empty the Thames with a tablespoon. Mere reduction of the temperature is of little value, and has a deleterious influence on the circulation. Ice packing gives too great a shock. In many cases of perityphlitis, in which there is no evidence of suppuration, medical measures should be preferred to surgical. The tendency to discard the use of opium he thinks is simply disastrous, and the foolish view that it should be denied must inevitably lead to a large number of cases being operated upon when such a procedure might easily have been avoided. In chronic renal disease, too, opium should not be denied. Bleeding in many diseases should be restored to favor; wet or dry cupping and flying blisters have their place in therapeutics. There is danger of overdoing the open-air treatment and the overfeeding practised in phthisis, and there is the greatest possible danger in the craze for the treatment of heart disease by baths and exercise. Gout can be better treated by the resin of guaiacum given in cachets than by modern methods founded on the uric-acid theory, the same drug being effective in rheumatism. The author would also call attention to the value of stimulating liniments in the joint affections of these diseases. Free purgation is less used than formerly in all cases, and in these days of self-indulgence and overfeeding this is a mistake. The author believes that there will be a reaction in favor of many of the methods of treatment which are

at present considered obsolete.—*Treatment*, February, 1903.

On the Use of Citric Acid in Uterine Hemorrhage.—The *Lancet*, March 14, contains the following: "In No. 8 of the present volume we gave an abstract of a paper read on this subject at the Royal Academy of Medicine, on January 13. Dr. Macleod, considering the introduction of a lemon into the cavity of the uterus to be a very novel, not to say an ingenious procedure, submitted it to the notice of the Westminster Medical Society, for the purpose, we suppose, of eliciting the opinions of the persons present respecting it. A discussion ensued: Dr. Granville expressed himself as opposed to the remedy, considering it to be unsafe and ineffectual Some gentlemen conceived that there would be great difficulty in getting the lemon out. It might be introduced easily enough, but how was it to be extracted? A silence followed: the question was so important that it required the most serious deliberation, and such it received. With the greatest imaginable gravity, and with the air of one "profoundly skilled in analytick," Dr. Copeland arose—Dr. Copeland, physician to the Queen's Lying-in Hospital, *cum multis aliis honoribus*—modestly suggested "that a small bit of string should be fastened to the extremity of the decorticated lemon, by the aid of which it might be safely withdrawn!' This suggestion was excellent; it dissipated all doubt and difficulty; it was a very *quod erat demonstrandum* of the question, and the society testified their approbation by great laughter and applause.

Successful Removal of 265 Centimeters of Gangrenous Intestine.—The patient of Roswell Park was a young man of twenty-one years. Abdominal symptoms called for operation which revealed a gangrenous condition of the appendix, about which three or four coils of small intestine had united themselves and adhered to the cæcum, and that all these adherent surfaces were in a gangrenous condition with threatening perforation at numerous points. At least four large areas of this character were found upon the small bowel, the uppermost being apparently near the middle of its length, *i. e.* a long distance above the cæcum. It now became a question whether to undertake several intestinal resections or to remove the entire length of bowel which contained these gangrenous patches. The patient's condition was bad and it seemed that the measure most indicated was that which could be most quickly performed.

Accordingly, a Murphy button was used and with it the ascending colon was connected with a loop of intestine just above the uppermost gangrenous area. The mesentery was then tied with a series of silk ligatures, and the entire section of small intestine involved was removed down to the ileocæcal valve. A considerable part of the cæcum being gangrenous the colon was divided at this point by an oblique incision, and in this way all of its gangrenous portion was removed. After the operation the portion of intestine which was removed was straightened out and carefully measured. Without undue stretching it was found to measure 265 cm.—8 ft. 9 in. The Murphy button did not come away until nearly four months after its insertion. The patient had a tedious convalescence, but eventually made a perfect recovery. —*Buffalo Medical Journal.*

Knife-blade in the Ear.—J. C. Thompson reports the case of a man of twenty-seven years who had had a bloody and purulent discharge from the right ear for seven weeks. Examination showed a mass of exuberant granulations in the meatus, bathed in a bloody pus. A probe passed through the speculum to press these granulations out of the way encountered a hard, rough, foreign substance, which felt like a piece of steel. After part of the granulations were curetted away a black substance could be seen in the external meatus. It was grasped with forceps and an attempt made to remove it, when it was found to be so firmly fixed that it could not be withdrawn. A hook passed behind it failed to dislodge the foreign body. Examination was then made behind and below the ear, and a foreign substance extending down an inch into the tissues of the neck could be plainly felt. When the projecting portion in the ear was moved by the forceps the portion in the neck could be seen and felt to move. Further questioning revealed the fact that the man had been stabbed two years previously. Under local anæsthesia through an incision behind the ear, there was removed a broken knife-blade more than an inch in length and of the usual width. The part projecting into the ear is very much corroded. That buried in the deeper tissues of the neck, while blackened, shows little signs of oxidation. It lay beneath the deep cervical fascia, and was partly imbedded in the fibers of the sternomastoid muscle—*Cincinnati Lancet-Clinic.*

Remarkable Case of Coma, Apparently Due to Acid Intoxication Sui Generis.—D. L. Edsall reports the case of a man of sixty-three years, who, while apparently in good health, was suddenly overcome by vertigo followed by coma, which lasted about ten hours. He was treated by alkaline transfusions. During this time he exhibited the symptoms and the urinary signs of acid intoxication. He then rapidly recovered and remained perfectly well. The signs of diabetes were absent at all times. The only satisfactory diagnosis that could be made in the case was one of cryptogenic acid intoxication, which was, in all probability of gastrointestinal origin. The man's tendency to digestive disturbance and the presence of such disturbance for some hours preceding his attack, made this source of the intoxication a likely one. He was completely saturated with alkalies in the treatment, receiving two and a half ounces of sodium bicarbonate intravenously; and his urine, which was tested with each portion passed, remained distinctly alkaline for about seventy hours after the alkaline transfusions were given.—*Indian Medical Record*, February 25, 1903.

Glycocholate of Soda.—Charles I. Hill, from a very considerable experience in the use of this drug, is convinced that it is of the greatest value in all cases of hepatic insufficiency, and that it is almost a specific in hepatic colic. It is contraindicated when the duct is occluded, as an increase in the amount of bile during this condition will increase the amount in the circulation. The dose is fifteen grains per diem, and upward, though the minimum dose is usually sufficient, as the drug should be administered over a considerable length of time, its effects not being observable till after a week or two of treatment. From its bitter taste it can be administered only in capsules, and even then it sometimes produces nausea for the first few days, which disappears if the medicine is persevered with, a few grains of magnesium oxide with the capsule will often prevent the nausea. Occasionally it produces diarrhœa at first, but after a day or two this also subsides. —*The Carolina Medical Journal*, March, 1903.

A New Anæsthetic.—At the meeting of the French Academy of Medicine, held on March 17, M. Courtade gave an account of a new local anæsthetic. It is para-amidobenzoin ether, and has been named anæsthesine. It is a derivative of orthoform, and is but slightly soluble in water, but freely so in glycerin and in fatty bodies. It is not poisonous, which gives it a great advantage over cocaine, while its action is much less transitory than that of that drug. M. Courtade has used the drug, especially in cases of patients suffering from tuberculosis or syphilitic ulceration of the pharynx which rendered swallowing very painful, or even impossible. After an application of anæsthesine in powder they were able to swallow without pain.—*The Lancet.*

Urates.—Young lady reading report of urinary examination: "Doctor, what are urates?" Doctor: "$5 per visit."

CRANIAL FORM IN MAN, TOGETHER WITH SOME REMARKS ON THE ATTITUDE OF THE PROFESSION TOWARD ANTHROPOLOGY.*

BY ARTHUR THOMSON, M.A. (OXON.), M.B., (EDIN.).

PROFESSOR OF HUMAN ANATOMY IN THE UNIVERSITY OF OXFORD; PROFESSOR OF ANATOMY TO THE ROYAL ACADEMY OF ARTS, LONDON.

WHEN first I undertook the delivery of this address I was uncertain with which particular part of my subject I should deal. For this reason I was led to select a title which would afford me the opportunity of varying the details of the matter I might possibly discuss.

There i no lack of interest or variety in the science which I have the honor to represent. The difficulty consists, rather, in the choice of such an aspect of this particular branch of knowledge as may appeal alike to those who are specialists and those whose interests are less technical, for I am anxious to lay stress upon the fact that even the busy practitioner may render immense service to science, if only he will accurately record the observations which often he alone has the opportunity of making.

I have no wish to delay you with a detailed reference to the history of medicine, but I may perhaps be permitted to point out that science owes much to medicine. It was Erasmus who described theology as the mother of the sciences. This may be true as regards the philosophies, but it can hardly be considered applicable so far as the natural sciences are concerned. When we remember how closely blended in the past, were the interests of the healing art with those of anatomy, physiology, botany, chemistry, and physics, we recognize how much each owes the other and how much the cultured physician of the time was of necessity an authority on, and oftentimes an exponent of these several branches of study. With the acquisition of knowledge, however, and the vast accumulation of new facts and theories, it became no longer possible for one man to attain proficiency in his calling and at the same time maintain a position as an authority on all or even one of these kindred studies. In consequence, we find that this state of things early led to specialism, and so, in course of time, these sciences became severed from and developed apart from medicine.

Of the more recent of the offspring of medicine we may cite bacteriology and anthropology.

It is of anthropology that I wish more particularly to speak; somewhat of a weakling, it may be regarded as the adopted child of medicine, a child possessing no very marked individuality, but displaying traits of character which certainly render it attractive. Its many-sidedness is the source of its weakness and the explanation of its lack of independence. It is little wonder, then, that it should have fallen to the lot of medicine to lend a helping hand to assist it through years of adolescence. Its growth is slow rather than feeble, and every decade marks a record of sure and steady progress.

It may not be amiss to consider for a moment why anthropology, in its physical aspect, should have fallen under the protection of medicine. Its processes and developments concern themselves with all that appertains to man, and no class is better qualified to assist in the solution of its problem than the profession whose lot in life brings it perhaps most intimately in contact with man in his different conditions and environments.

A skilled observer by education and training the doctor in the performance of his duties is brought into relation with aspects of human nature denied to most others. A pioneer, as much as the missionary, he is ever in the front rank, seeking to soften by the exercise of his art, the harsher visitations of nature. His work and eagerness for information often lead him into regions hitherto unexplored, whilst his skill in the relief of suffering usually enables him to win the confidence of those who have profited by his assistance. Thus he has opportunities of studying man which the zoölogist or the lay explorer can never rival. But although I have laid stress on that aspect of his work which leads him far afield, along the untrodden paths, I would have you bear in mind that even the more familiar walks of life there is much for him to do. He is the constant witness of the ever-varying influences of nature, operative from birth through adolescence to old age and death. The examination of his patients provides him with opportunities for studying their bodily characters and peculiarities in a manner unavailable to others; whilst his observations of disease, nutrition, food, soil, and climate enable him to form an especially valuable estimate of the influence of environment on the individual and on the community. In matters of heredity too his experience often ranges through three and sometimes four generations. For all these reasons the medical man is especially well qualified to play an important part in the development of physical anthropology. He has done so in the past, and there is every reason to hope that he may continue to do so in the future. What is wanted is more coöperation and greater unity of purpose. Whilst individual observations are always valuable, some attempt should be made to combine in research Just as nowadays the inquiries into cancer and tuberculosis are being conducted in a systematic manner, so, many of the problems of anthropology can only be solved by united effort. I am aware that various attempts have been made in this direction, but the great mass of the profession has never been approached to share in the work. I cannot help thinking that if medical men in various parts of the world were requested to furnish such data as were wanted, by a duly elected and properly constituted central authority, much useful information would be acquired, whilst it would lend an added interest to the professional duties of those who helped. The appointment

*Address delivered before the International Medical Congress, held in Madrid, Spain, April 23-30, 1903.

of an international committee of experts would be the first step toward the realization of such a scheme. Were any such plan adopted it seems to me imperative that those whose coöperation is sought should be instructed regarding the relation to the enquiry of the facts they are requested to record. In this way you are more likely to obtain satisfactory results than if you merely propound questions and expect answers.

I may perhaps best illustrate my meaning by taking a somewhat detailed example. It is natural that I should select a branch of the subject to which I have been devoting considerable attention lately, and whilst I would by no means presume to hint that it is of all others the most important, yet it will serve to enable me to point out lines of inquiry which might with profit be pursued by those who are actually brought in contact professionally with peoples of different nationalities and race.

The subject I propose with your permission to discuss is the vexed question of cranial form and the significance of the cephalic index. I know full well that the matter has engaged the attention of many more competent than I. Yet I think there are aspects of the question which have been overlooked, or at least insufficiently commented on, and that must be my excuse for venturing to address you on what at first sight seems a threadbare topic.

For purposes of convenience, it may be well to group the influences at work in the determination of cranial form under two heads:

(*a*) Those operative from within.

(*b*) Those operative from without.

The former includes such factors as volume of brain, growth of sutures, and ossification of bones, compensation as to balance of head, heredity and breeding. The latter embraces muscular influence dependent on jaw development more or less intimately related to the size of the teeth and consequently associated with diet. In this way environment plays a part in the modification of man's cranial form in the same manner as it is productive of the variety of shapes met with in other types.

I propose to deal with the mechanical influences enumerated under (*b*) first, because I shall have most to say on this subject, and because, if novelty there be in any of my observations, it is mainly concerned with this aspect of the question.

The time at my disposal is so short that I can only touch very briefly on some of the points which require consideration.

In regard to the teeth, it is obvious that large teeth must require large jaws. Abundant proof has been furnished by Flower and others that the races of mankind display remarkable variety as regard the size of their teeth. Large teeth are characteristic of the lower races, whilst small teeth are the attribute of the more highly civilized types. Apart, however, from the size of the teeth, testimony is not lacking to prove that a reduction in their number is also taking place. The tendency for the wisdom molar to disappear is much more common in the higher than in the lower races, and when we remember that examples are not wanting of jaws in which a fourth molar has been present on each side, there appears ample justification for the assumption that a reduction in the number of molars has already taken place and is still in progress. But it is not only the wisdom teeth which occasionally fail to appear the lateral incisors also in some cases abort or are never developed. If then the number, as well as the size of the teeth, is undergoing a reduction, it cannot but be doubted that this must be accompanied by a diminution in the size of the jaws. Other reasons have been assigned to explain the development of the mandible, such as its use for prehensile purposes, its growth in association with the tongue, and the changes induced by the altered conditions of the circulation referred to by Fauvelle,[1] but none of these need seriously affect the issue since none can compare in potency with the influence exercised by the teeth. This is perhaps best illustrated in the case of the apes during the period of the eruption of the permanent dentition, when as Hüter[2] has pointed out, a great increase must necessarily take place in the molar sedgment of the body of the mandible to provide accommodation for those teeth which are not represented in the milk dentition. The changes which are so characteristic of the apes one would naturally expect to see displayed in the case of man, but here, unfortunately, the evidence is somewhat conflicting. Pruner Bey held that at birth the negro child displayed no prognathism, whilst Hrdlicka asserts that the face of colored children is generally more prognathic than that of white. Here, then, is an instance of the necessity for further information.

Although we accept it as correct that large teeth necessarily require large jaws, it by no means follows that the jaws are more projecting. A moment s consideration will enable you to realize that, given an equal alveolar length, two jaws may display quite different appearances, in one the curve may be of the parabolic type with consequent projection, in the other it may assume an elliptical form with less forward thrust. In one the jaw will be associated with a narrow, in the other with a broad face.

But whilst we have seen that the jaws are liable to many varieties of size and shape due to alterations in the number and magnitude of the teeth, we must also consider what effects these changes will have on the development of the muscles connected with the mandible.

The extent and development of these muscles lead to many variations in the form and extent of the temporal fossæ, to mention only one instance of muscular attachment: and no one who has examined a series of mammalian or avian skulls but must have been struck by the remarkable modifications in the cranial shape induced by a greater or less development of the muscles of the jaws or beak.

As Dr. Keith, to whom I am indebted in this inquiry for much valuable assistance, has pointed out, the expansion of the temporal area over the side of the skull in the anthropoids is correlated with the developing jaw and the eruption of the permanent teeth. In this group of animals the changes induced are very manifest, because the results are not masked by undue expansion of the cranial cavity. In the anthropoids the average cubic capacity of the adult exceeds that of the young animal by from 50 to 150 ccs., whilst in man the difference between the cubic capacity of infants a few days old and children of fifteen years of age amounts to 978 cc. (Topinand). As we will see hereafter this expansion reacts on the influence of the temporal muscles.

Whilst these facts have been widely recognized and their influence more or less directly referred to, so far as I am aware, no attempt has been made to estimate their value as determining factors in the production of cranial form. Nor need we be surprised at this since the methods of mensuration of the lower jaw now, apparently, universally adopted by Craniometrists is one altogether useless to enable us to analyze the mechanism of the jaw and its muscles. The only paper to my knowledge, dealing with the lever like action of the jaw is one by J. Gorham.[3] In this, however, the author was con-

cerned with the arrangement and the form of the teeth as set in the jaw, and the forces necessary to raise them. In the present instance we are concerned not so much with the forces exercised on the jaw, but with their secondary effects on the parts from which they arise.

The width between the condyles of the jaw is, necessarily, correlated with the width of the cranial base. The condylo-symphisiaz length, which is the measure of the distance between two verticals passing in front of the symphysis and behind the condyles whilst the jaw rests by its body on a horizontal plane will indicate pretty precisely the long arm of the lever. By comparing this length with the intercondylic width—100 we get what for convenience, may be termed the mandibular index.

$$\frac{\text{Condylo-symphisial length} \times 100}{\text{Intercondylic width}} = \text{Mandibular index.}$$

I find this index ranges from 70 to 100; when the index is high it means the jaw is long proportionately to its width, whilst when the index is low the jaw is short, relatively to its width. Grouping together my results it appears that thirteen brachycephalic skulls yield an average mandibular index of 84.8, eleven mesaticephalic skulls an average of 88.3, whilst twenty dolichocephalic skulls yield a mandibular index of 90.6. There is this distinct proof of a correlation between jaw length and head length.

Discarding for the time being the influence of the other muscles closing the jaw, and confining our attention to the temporals only, it is obvious that a long jaw will require a more powerful muscle than a short jaw to produce the same result at the "bite," provided the force is applied at the same distance from the fulcrum. Were such the case, the problem would be fairly easy, but, unfortunately, nature provides compensation by varying the position of the point of application of the force. Assuming that the tip of the coronoid process represents the poin of maximum intensity of the power exercised by the temporal muscle, we find that the distance of that point from the axis of rotation of the temporo maxilary articulation varies considerably in individual jaws.

The length of the short arm of the lever may be somewhat roughly estimated by measuring the distance between the posterior edges of the condyle and the tip of the coronoid process. Reducing this to its proportion to the length of the mandible (condylo-symphysial length) we can obtain an index, thus:

$$\frac{\text{Condyo-coronoid width} \times 100}{\text{Condylio-symphysial length}} = \text{Coronoid index.}$$

This enables us to determine the proportion of the short arm of the lever to the length of the long arm. I find from comparison of the specimens I have examined that this index ranges from 43 to 31. That is to say, assuming that the force is applied at right angles to the lever and also that the coronoid process always lies in the same horizontal plane as the lever, the jaw with a high coronoid index will act, provided the same force is applied, with proportionately greater advantage than one with a low coronoid index; for in the case of the jaw with a high index, the force is applied at a point further removed from the fulcrum than in a mandible with a low index. In estimating the amount of force necessary to effect the same result in the masticatory apparatus of two skulls, we have these two factors to consider: First, the length of the lever or jaw as a whole, and second, the disposition of the force on that lever. The subject thus becomes much more complicated than before, for an examination of a considerable number of specimens proves that these two factors do not always interact upon each other in the same way. Thus we may have a long mandible which will obviously require the exercise of greater muscular force to discharge its functions, were it not that this is compensated for by the fact that that force is applied at a point more remote from the fulcrum. On the other hand a jaw of similar porportions, owing to the fact that the coronoid process lies closer to the condyle, will require a much greater muscular effort to produce the same result.

There seems to be a correlation between the coronoid index and the cephalic index, for I find that the higher coronoid index is more usually associated with dolichocephaly, whilst the lower coronoid indices are met with in skulls of the brachycephalic type. The number of observations, however, is too few to draw any conclusions from, and further data are required before we can arrive at any definite result. Since, then, it appears that we are unable to harmonize the counteracting influences of the two factors at work, it occurred to me that perhaps the best way to attempt the solution of the question would be to determine experimentally the amount of force necessary to overcome the same amount of resistance in jaws from different skulls the measures of which (the skulls) were known.

As the reader will understand, my object in thus studying the mandible has been to attempt to estimate in each particular skull the amount of force exercised by the temporal muscle to produce a like result. Were we successful in doing this we should be able to form some idea of the relative developments of the temporal muscles, and thus see whether, as I have already hinted, this development of the muscles has any correlation with the cephalic index, and if that be so, whether we are justified in regarding it as one of the predisposing causes in cranial formation. For this purpose I devised an apparatus, details of which are published elsewhere, which enabled me to estimate with fair accuracy the amount of force necessary to overcome a similar resistance applied over the incisor teeth of the jaws I experimented with. Thus I found that the weights necessary to act as a counterpoise to the jaw loaded with 100 grams placed over the incisor teeth or at the "bite," ranged from 320 to 448 grams. In other words, assuming that we closed the jaws with a force equal to 100 grams at the incisor teeth, we would require to exercise a muscular effort equal to from 320 to 448 grams. And if at the same time we neglect the influence exerted by the other elevators of the jaw, we may regard this as some index of the development of the temporal muscles. Such being admitted, it must also be obvious that a corresponding force will be exerted over the area from which the muscle arises. Granting that this be so we would naturally expect a correlation between the weights recorded and the cranial form, assuming of course that we are prepared to admit that the shape of the head can be affected by any such influences.

Happily for my argument, we find this view abundantly supported, for whilst the brachycephalic skulls average a weight of 370 grams to counterpoise their jaws loaded to the extent of 100 grams, we find the dolichocephalic skulls require a weight of 390 grams to produce a like result under similar conditions—that is to say, a difference of over 5 per cent. in the amount of forces necessary to produce the same effect in the two types. Now when we consider the large amount of force a healthy man can exert by closing his jaws, it will be at once recognized that the amount of effort necessary to produce this result will vary very greatly; in other

words, that the dolichocephals are, as a rule, furnished with more powerful temporal muscles than the brachycephals, and further, since we have already shown that the mandible of the long-headed races is more projecting than that of the round heads, we are justified in assuming that this increased muscularity is necessary to overcome the mechanical disadvantage at which so long a lever acts.

I will not dwell on this aspect of the question further than to remind you that the sides of the cranial vault to which the temporal muscles are attached are the parts of the cranium which are most intersected by sutures of a complicated arrangement. We can therefore readily understand how this, the region of the pterion, is less able to withstand long-continued pressure, or perhaps it would be better to describe it as that it is more susceptible to the influence of prolonged stress.

Passing now to the consideration of the causes operative from within, I need say nothing of the influence of sutural growth except to refer to the recent work of Papillault,[4] who has shown that the occurrence of the metopic suture is more common among races with large c anial capacity, and is due to a superiority in the bulk and relative weight of the cerebrum.

What I should particularly like to lay stress upon are the observations of Boas [5] in regard to the cephalic index. That distinguished anthropologist has succeeded in establishing certain correlations which are most valuable. Thus he shows that the diameters of the skull are primarily determined by its capacity, the height appears to be most closely associated with the capacity, the length least so. On the other hand the correlation between the breadth of the face and the horizontal diameters of the head shows the two transversal diameters to be very closely correlated, while the length of the head is more closely correlated with the height of the face. Boas further states that when capacity is introduced into our consideration of the question a compensatory growth is found to exist between the breadth of the head on the one hand and height and length on the other. "The relation between capacity and head diameters is found to be of fundamental importance, and among these, the relation between the transverse diameter and the capacity is most significant."

Failing the time to refer to other considerations of interest in this connection I must content myself with drawing your attention to the confirmation these views receive from those classes of pathological cases in which there is either a diminution or an excess in the volume of the cranial contents. I refer to microcephaly and megacephaly of a hydrocephalic type.

The apelike characters of the former have frequently been referred to, whilst the "old fashioned" or intellectual appearance of sufferers at an early stage of the latter disease has often been remarked upon. For our purpose it is important to note that these appearances are entirely dependent on cranial capacity. The microcephal is usually a pronounced dolichocephal of a simian type, whilst the chronic hydrocephal usually displays the appearance of exaggerated brachycephaly. Perhaps one of the most interesting points in connection with both these classes of cases is that while the cranial vault, *i. e.* that part of the calvaria developed in membrane, displays great variation in form and size, the cranial base, *i. e.* that part of the skull ossified in cartilage, shows little evidence as a rule of much alteration of its relative proportions.

It seems we have thus an explanation of how by increase in the volume of its contents the cranial capacity can not only be enlarged, but the shape of the cranial envelope modified. One might have expected to have obtained confirmatory evidence of these views by noting the changes which occur in the form of the head attendant on its increase in capacity during growth. The evidence adduced, however, is very conflicting, whereas some observers maintain that, as the child grows, its head increases to a proportionately greater extent in the transverse diameters, others assert that increased relative length is the rule. Both are probably right, and the discrepancy between them is due to the fact that their observations have been made on different tpyes, types in which the various factors interact differently so as to produce different results. Here we have an admirable instance of the kind of information much desired and surely readily obtainable, if only the want was proclaimed. It is highly probable that a negro child's head is much rounder than it is in the adult, in this respect resembling the anthropoids, whilst the head of a white infant is probably more elongated than it is in after life. The changes being due entirely to differences in cranial capacity and the influence of the masticatory apparatus, until such evidence is forthcoming, however, it would be rash to venture upon any conclusions.

Considering the membranous nature of the cranial vault during growth and development, as contrasted with the cartilaginous base, it stands to reason that the vault will be reacted on more readily than the base; and given a cavity of oval or elliptical form with elastic walls, the more its contents are increased the greater will be its tendency to assume a spherical shape.

That man is descended from a pronounced dolichocephalic type with a cranial capacity lower than that of any existing race is generally conceded, it follows that the modifications in shape consequent on an increase in the volume of the brain will tend toward sphericity; in other words, the cranium will become rounder. All the evidence seems to point this way, and although there may be some who doubt the validity of such an argument, they will, I trust, be convinced with the proof I now propose to supply.

It occurred to me that it might be possible experimentally to test the influence on the form of the skulls of those mechanical agencies which we have just discussed. This I have done, in the models which I show you. In these, the vault and sides of the cranium have been cut away, leaving only the base. To this has been cemented a rubber bladder which can be inflated through a tube passing through the foramen magnum. To the sides of this bladder have been cemented a number of silken cords arranged as are the fibres of the temporal muscles. By affixing weights to these, or by putting a strain on them, we can exert an influence over the area of the bladder to which they are attached, comparable to that which the temporal muscles exercise on the cranial walls. We are thus provided with a means of testing the changes induced by increased capacity, for by altering the degree of this tension of the bladder we can simulate pretty closely the natural process. We can further test the influence exerted by the temporals by putting a strain on the fibers of the imitation muscles in the model. Let me now proceed to demonstrate what takes place in these models under different conditions. I have one model here in which the temporal muscles are not represented. On this we can test the influence of increasing distension on the cranial envelope. With just such an amount of air within the bladder as is

necessary to slightly distend the walls we obtain a form which is distinctly reminiscent of the anthropoid apes. The internal pressure is not yet sufficient to distend the forepart of the cavity, and in consequence, the brow ridges remain prominent and outstanding, whilst the shape assumed by the vault is that of pronounced dolichodephaly. On increasing the internal pressure by the injection of more air, the frontal region becomes gradually inflated, with consequent gradual disappearance of the prominent supraorbital arches. In fact, as the internal tension is increased, the envelope alters so as to display successively the contours associated with such types as that of pithecanthropus and the skulls of the Neanderthaloids and Australoid races. As yet, however, the vault preserves its elongated and narrow form, thus exhibiting in almost every detail the characteristics of the skulls of what may be termed the primitive races of man. On proceeding still further with the inflation of the balloon, the expansion, whilst general throughout, particularly affects the height and width of the vault, passing through all the stages of decreasing dolichocephaly, through mesaticephaly to pronounced brachycephaly. The consequent elevation of the frontal region at length causes the entire obliteration of the projecting brows, and the appearance presented by the model displays all the features of a skull of elevated type.

It may be argued that the foregoing experiment proves nothing, yet whilst admitting that the means employed are only a crude imitation of Nature's processes, it must be conceded that the model displays in a very striking manner the appearances exhibited by skills of different types.

The cause of the production of the supraorbital ridges and their subsequent disappearance by the further distension of the cranial cavity is most instructive. We see now the necessity for the massing of the bone in this region in skulls of small cranial capacity. The craniofacial axis is as essential to the face as it is to the calvaria. A reduction in the size of the latter does not necessarily reduce the length of that base from which the skeleton of the face depends.

As a consequence, however, of the reduction of the size of the cranial cavity, the bone over the orbital ridges must be thickened in order to afford a base of resistance, through the superior maxilla, against the bite of the mandible. When, however, the distension of the cranial cavity leads to an expansion of that space over the orbits and a consequent elevation of the frontal region, the necessity for this heaping up of the bone over the brows disappears, since the orbital and ascending plates of the frontal bone are now disposed at such an angle as to enhance greatly the strength of this part of the skull without entailing so much bony deposit.

The experiment further demonstrates the gradual transition from the dolichocephalic to the brachycephalic form which accompanies increased cranial expansion. It seems absurd, after this exhibition of the influence of internal pressure, to discuss the independent origin of the dolichocephalic and brachycephalic types. Everything points to the dolichocephalic as being the older stock, and though it may have taken many thousands of years to have evolved the rounder head of races, we have only to consider the evidence adduced in connection with hydrocephaly, and the facts demonstrated in the above experiment, to realize how readily this transformation may occur and how intimately it is associated with increased internal capacity.

Whilst undoubtedly the influence of capacity is of paramount importance in man we can study in the models the modifying influence of the temporal muscles by exercising a certain amount of traction on the silken fibers which represent these structures. This is best done by the application of weights, and, as the results show, considerable alterations are effected thereby. As will be seen, the effect

SERIES 1. Bladder slightly distended with air.

Series 2. Bladder moderately distended.

Series 3. Bladder considerably distended with air.

produced varies with the degree of distension of the capsule and the amount of weight employed, and whilst the results are not so striking as might be expected, still they are sufficient to prove that there must be taken into account in considering they varieties and subtilties of cranial form to which, of late, Sergi has directed special attention.

Further, as will be seen, the results differ accordingly as different parts of the muscles contract (as represented by the tension exercised on the silken cords). Now an examination of skulls of different types clearly demonstrates the fact that the expansion of the area of attachment of the temporal muscles does not always take place in the same direction. Some tend to rise on the side of the cranium, whilst others spread further backward. In this connection there seems reason to believe that the posterior fibers of the muscle are better developed in those who use their jaws in a grinding fashion, and probably this is correlated with the wear of the teeth so characteristic of certain races. No doubt the tough and gritty nature of their diet may to some extent explain the attrition of the teeth in certain races, but it would also be a direct cause of the more powerful grinding movements necessary to reduce the food to pulp, thereby increasing that part of the muscle more particularly concerned in the grinding movement. Be that as it may be, the fact remains that, when in the model the capsule has been distended so as to assume an ovoid form, an increased traction of these posterior fibers at once converts the shape into that of an ellipsoid.

The time at my disposal has prevented me from touching on many subsidiary details of no little importance, nor have I been able in this general survey to refer, in even a general way, to the researches of others. My endeavor has been rather to prove that the shape of man's head in his higher developments is the outcome of those physical and intellectual environments which have led, on the one hand, to the reduction in size of his jaws, and on the other, to the increased volume of his brain. These attributes are perpetuated by the influence of heredity and modified by cross-breeding and the laws of natural and sexual selection, but there is no constancy about them. Primarily they are dependent upon the physical forces which we have just discussed. We have I trust been able to trace the gradual ascent in the form of man's cranium from one group to the other; thus disposing of the necessity of explaining the existence of the dolichocephalic and brachycephalic types as due to independent origins.

Furthermore, I have endeavored to show how the confirmation of this solution of the problem of man's varied cranial form can be assisted by the careful and accurate records of those in practice, who have opportunities of noting the changes in jaw form, and head shape, during the periods of growth from infancy to maturity.

In conclusion, let me say that, as regards the cephalic index, I am in entire agreement with Professor Boas, who considers that whilst that index "is a convenient practical expression of the form of the head, it does not express any *important anatomical* relation." My own observations entirely confirm his view that the relation between capacity and head diameters is of fundamental importance, and that among these the relation between the transverse diameter and the capacity is the most significant.

RECIPROCITY IN PATHOLOGY.*

By S. B. LAACHE, M.D.,
CHRISTIANIA, NORWAY.
PROFESSOR OF PRACTICE OF MEDICINE AT THE KONGELIGEN FREDERIK'S UNIVERSITET.

General Considerations; Reciprocity as a Universal Law; Reciprocity in Morbid Processes; Alternations between Diseases.—Permit me, gentlemen, to express to the Committee on Organization of the Fourteenth International Congress at Madrid my appreciation of the honor they have accorded me. In the reunion of so many specialties, differing, yet, at the same time, related; at a period when the question of boundary lines (Grenzgebieten) is in the order of the day, in the choice of a subject, I have found none more fitting than the great law of reciprocity, of which, however, it will only be possible to outline the salient points.

As you know, nothing is lost in nature; there is but a change of form. So it is in history; the events of the present must be viewed in the light of the past and future; of preceding events and consequences which will follow them. If it is thus with nations, so it is with individuals considered singly; action and reaction are shown in small things as in great. One strikes and is struck. "Kämpf und Gegenkämpf erhalten das allgemeine Leben," wrote the learned Jesuit, Athanasius Kircher (1598–1680),[1] now as then, one sees attraction and repulsion wherever one turns; ideas clash and cross, art is inspired by science, and *vice versa*: the sciences themselves impregnate one another, and it is not generally difficult to place one's finger upon the thread which binds them together.

That which concerns us now is not this universal reciprocity, nor scientific reciprocity in general, but only a part of the latter: that which relates to our own science, medicine, in which general repercussion is at least as pronounced as in any other sphere; and it is a living being who forms the basis of it.

The consideration of the human body as a purely physical apparatus has long since been abandoned. The resemblance to perfect watch works, in which each wheel must be exactly adapted to the other in order that the movement of the whole shall be perfect, may not be denied; but the comparison halts here, for a relatively slight disorder suffices to arrest the inert machine, which has not the power to effect spontaneous repair, while it is quite otherwise with the living machine. Certainly the resistance of the latter may be compromised by a given lesion, but more often than not it will continue, even in the face of grave disorders, to do its work. To account for this fundamental fact, it must be recalled that the normal human organism has at its disposal a reserve fund, by means of which compensation is established; or, at the worst, an accommodation to circumstances. This constitutes the most interesting chapter in pathology—a chapter to which the greatest minds have devoted exhaustive study.[2]

We now come to the consideration of the influence of various morbid processes upon one another: for example, necrosis and inflammation—the former preparing the way for the latter, as in circumscribed peritonitis in which inflammatory reaction opposes a barrier to gangrene which might otherwise be progressively fatal. Thus it is also among pathogenic agents which may react upon one another; the antagonism being in general, however, but relative, as between paludism and tuberculosis (Rokitansky),[3] between the latter and can-

*Address delivered before the Fourteenth International Medical Congress, Madrid, April 23-30, 1903.

cer,[4] etc. On the other hand, pathogenic agents associate themselves in full accord, and engraft themselves one upon the other, as in diphtheria and scarlatina, or in the secondary pyogenic infections. Acute diseases have cured chronic affections. This has happened in the superposition of erysipelas upon a subjacent exudate. A general infection has sometimes exercised a favorable influence, as typhoid fever occurring in a syphilitic. Certain necroses may also disappear in the course of divers fevers.

Unfortunately, the new disease often represents but an alternation with the old rather than a permanent cure. Thus it is that upon cessation of the new malady, the old returns in full force. On the other hand, it cannot be said that the temporary influence is always good. Tuberculosis especially, for example, may be most unfavorably influenced by infectious diseases, such as diphtheria. We must, however, abandon the more detailed consideration of bacteriological symbiosis or antibiosis, etc., as well as the pathological reciprocity existing between men and animals, and take up the relations existing, from the clinical point of view, between the different organs and systems of organs.

Reciprocity between Organs; the Internal Secretions; the Heart and Blood Vessels; the Abdominal Organs; the Nervous System; the Skin.—The means established are: Mechanical pressure from simple contiguity, the blood, lymphatics, glandular system, and nerves. Some light is thrown upon these questions through a study of the internal secretions; as, for example, those of the thyroid, suprarenal capsule, hypophisis cerebri, etc. The discovery made by my compatriot, Ramm, of atrophy of the prostate following castration, has an undoubted scientific value.

In studying these various systems, the attention is naturally directed to the heart as the site *par excellence* of reciprocity. This organ, as the center of the vascular system, constitutes one of the most important centers of the whole body; the centrifugal forces which emanate from the heart and the centripetal influences directed to it, succeeding one another without ceasing. In other words, the influence of the heart is felt everywhere and its working instrument, the blood, that "fluid" organ, is a means of transport between the different parts of the organism; while the alexins, or according to Metchnikoff's ingenious idea, the leucocytes, form our defense against anxious influences, toxic or infectious.

If now we pass to the abdomen we find that the displacement of these organs gives rise to Glénard's splanchnoptosis, which may be said to result from a letting down of the very walls of the edifice; the condition of the tisues being comparable to dead, inelastic matter, as contracted with the living elastic. Of great import are the relations existing through the blood and nerves between the peritoneum and the digestive tract and between the various parts of the latter; notably between the intestine and the stomach. As a rule, not however without exceptions, a disorder of the stomach—the organ of preparatory digestion—is accompanied by irregularities in the function of the large intestine, the organ of defecation, and *vice versa*. The study of perityphlitis, always in the order of the day, and pursued with so much zeal and perseverance, has brought to our knowledge many affections called appendicular, among which may be mentioned the larvated appendicitis of Ewald[5], which simulates and may be mistaken for a simple dyspepsia; and in this there may even occur hæmatemesis.[6] Anomalies of the gastric juice are far from rare in intestinal disorders, and an analogous condition is seen in acute paralytic dilatation of the stomach following laparotomy. On the other hand, certain reflex intestinal affections may be brought about by acting upon the gastric mucosa, as has been seen in the occurrence of ileus after lavage of the stomach. Finally, how can one account for the perfect digestion sometimes seen in gastric anacidity, unless it be admitted that the pancreas can take up the task alone?

The circulatory center of the abdomen is the liver. G. E. Stahl (1660—1734)[7] was, two centuries ago, the harbinger of our modern theory of autointoxication when he qualified the portal vein as the vena malorum. The liver constitutes, in asystole, the great reservoir for the retrograde blood column. The hepatic influence upon digestion was brought fully to light by the English when they gave the name of "liver diseases" to morbid conditions which, upon the continent, are prone to be attributed to the stomach. In our time the study of hepatic insufficiency[8] will no doubt contribute to the clearing up of obscure points in pathological physiology. Certain it is, that the liver, robbed of its former importance, is on the way to a reaquisition of its early prestige. With the pancreas it formed originally from the autogenous as well as the physiological point of view, a unique *ensemble*; the hepatopancreas; and now that they are anatomically separated, pancreatic diabetes as well as pancreatic necrosis with fatal hemorrhage point to the connecting links between the two organs.

Compared to the liver, the rôle of the spleen has been generally considered a subordinate one, dependent upon the portal vein; but Bant.[9] has recently described a splenomegalia as the antecedent of hepatic cirrhosis, and contemporary literature contains confirmatory observations of this nature. I myself having a few years since had a well-defined case of this kind, although I must add that the diagnosis was not confirmed by autopsy.

Nevertheless, if our knowledge of the spleen is rudimentary, this is not true of the kidneys, which through their daily diuresis constitute the manometer of cardiac labor. Thus Huchard[10] declares that, in arterial cardiopathies, the disease is in the heart and arteries, the danger in the kidneys. Their relation to the liver is most intimate by reason of the rôle they fill as the great emunctories for the waste products of nutrition formed in the liver. This is why puerperal eclampsia was formerly considered a renal affection, though now there is a tendency to attribute it to the liver,[11] and it can scarcely be doubted that there is a hepatogenous albuminuria.[12] This by no means lessens the importance of the kidneys, especially in relation to albuminuria; the frequency with which the latter occurs in the most diverse affections, shows the prominence of the rôle which these organs play; while their insufficiency brings in its train a legion of pathological processes. In unilateral lesions[13] the influence of the diseased organ upon the healthy kidney, due probably to the "reno-renal" reflex of Guyon, is of great importance, and is analogous to sympathetic ophthalmia,[14] though probably springing from a different cause.

It remains to us to take up the nervous system, the *sine quâ non* of physiological and pathological reciprocity, both general and special. As the nerves are in reality the life of the organs, regulating their movements and secretions, so the majority of affections react upon the nerves, be this reaction evidenced but in pain of greater or less intensity. The broad conception of general insufficiency—the atony of older writers—in the widest sense of the

expression, can be traced, for the most part, to defective innervation. It is through the nerves and reflexes that communication is established between the most widely separated parts. What an inexhaustible source is the domain of the nervous system in its bearing upon the subject of reciprocity! What a proof of precision in the harmonious play of intellectual forces is offered in a study of the various forms of aphasia! Finally, what marvelous coördination is required in the execution of voluntary movements, as for example, in walking!

Aside from the internal organs which we have rapidly passed in review, there is an external one which merits special mention; that is, the skin, which not only protects us from outside, hurtful influences, but which also, with its variations in appearance, energy of its functions at various ages and insensible perspiration, is in relation with the body functions in general and with each viscus in particular. This applies, above all, to the kidneys, but also to the respiratory and digestive mucosæ; the latter, which forms, from the embryological point of view, the endoderm, in contradistinction to the ectoderm, may literally be reflected upon the external surface. For example, we may mention pruritis due to internal causes [15]; cutaneous eruptions in uræmia, diabetes, digestive circulatory, respiratory and genital disturbances, as well as those due to infections, toxins and medicaments, and exanthemata due to serotherapy, pigmentations, etc., all of which are the visible expressions of internal influences. On the other hand, the effect of external influences acting within may be seen in duodenal ulcers occurring after extensive burns. Further, the skin exercises, by virtue of its wealth in blood vessels and blood, a marked influence on heat regulation, and is consequently concerned in the pathogenesis of fever and those most frequent and trivial affections, colds.

The Organism as a Unit; the Vicious Circle; the Defensive Circle; Therapeutical and Prophylactic Conclusions.—If, in looking back, we desire to draw deductions from the development of our subject, the facts we have gathered together—and which it would not be difficult to multiply—suffice to prove that, as has been frequently said, the various branches of medical science, whose domain extends from day to day, are more or less closely allied; while the various parts of the living organism form one great whole, though like the States of a federal republic they retain a certain autonomy. This is the reason why at the bedside of the patient we frequently find ourselves confronted with a malady which is not strictly localized in the affected area, even though complications may not exist. Not always is this so. On the contrary, and here pathology contributes largely to the elucidation of physiology, pathological groupings show that physiological affinities are directed by conducting forces through which the association of two or more organs is brought about. Notably in the domain of the great centers do we find groups of symptoms which we call syndromes. Of prime importance are the cardiac syndromes, such as the cardiopulmonary, cardiohepatic, cardioarticular, cardiorenal, etc. [16], the latter furnishing in granular atrophy of the kidney one of the best examples of reciprocal localization. While the affection known as permanent slow pulse, a malady which, as you know, is characterized by repeated epileptiform or syncopal attacks, constitutes the cardiobulbar syndrome, the respiratory type known as Cheyne-Stokes belongs to the bulbopulmonary. In the domain of the liver we have the syndromes known as the hepatorenal, hepatogastric, hepatoperitoneal, etc.

But aside from these syndromes and many others which might be mentioned, among which the cerebroabdominal should not be omitted, and of which Trousseu's gastric vertigo is an example, there are many other affections which must be taken into account, even though their anatomo-pathological nature is not clearly understood. For example such apparently trivial affections as a mild catarrh, a slight neuralgia, a temporary indigestion, etc., may suffice to affect the well-being of an individual otherwise healthy; the organism as a whole reacting to the condition. From this point of view G. H. Roger[17] is assuredly in the right when he maintains that no malady remains localized. And yet, by reason of reciprocal reaction, a localization or limitation may be brought about, as was stated in the beginning of this article. It is undoubtedly true that to a primary lesion a secondary affection is too often added, to the detriment of the organism, yet, on the other hand, reciprocal reaction may be exerted in its defense; a collaboration of labor being thus established, so that through a double or multiple alliance of forces, a defensive rather than a vicious circle is formed. As an example, aside from the limiting peritonitis already mentioned, we might cite certain pleuritic exudates; thus a hitherto progressive phthisis may be arrested, even though temporarily, by a pneumothorax. In my personal experience such an arrest has persisted as long as ten to thirteen years. The relative immunity to pulmonary tuberculosis enjoyed in certain cardiac affections, as noted by Rokitansky, [18] should be mentioned in the same connection. And when such a defensive circle is established, the physician's first principle should be—as Jacoby[19] declared nine years ago, at Rome—*non nocere*, it is the duty of the conscientious physician, I repeat, to respect this circle, and when possible, strengthen it. And what is more, the theory of so-called "salutary" diseases has given rise to new therapeutic methods, in combating one disease with another [20]. Thus it is that since the early studies of the late Cantani, bacteriology, in its steady progress, has given birth to serotherapy, of which Jenner's vaccination was the classical precursor.

Very often a disease cannot be attacked directly; one must strike it obliquely, that is through reciprocal action. In pneumonia, for instance, the treatment is generally directed to the heart; and the latter in turn is reached, in cardiac affections, through the blood vessels (the peripheral heart, as Huchard says); vasoconstriction being, as we know, an indispensable factor in the action of digitalis. And again, we seek to lessen the heart's burden by bleeding; having in view the reduction of blood-pressure and dilatation of the peripheral vessels. In line with the present argument is the utilization of the skin in combating internal affections through the application of hydrotherapy, vesication, and counterirritation.

I might continue further, but I will limit myself to a few words concerning opotherapy, or the substitution treatment which is the creation of Brown-Séquard, and which has yielded such brilliant results in myxœdema. But experience in this line of treatment shows that a therapeutic measure, rational in itself, may fail of its proper effect and even do more harm than good. It must not be forgotten that organic extracts are not altogether inoffensive preparations, and their use should not be lightly extended to unknown domains; and, above all, it is to be hoped that the warnings heard against the indis-

riminate use by the public of thyroidine for obe-ity[21] will be seriously considered.

But, as you know, "prevention is better than ure." From all that has been said, it is not diffi-ult to gather many prophylactic suggestions. Pro-hylaxis should have in view the increase of per-onal resistance and should seek to favor the har-nonious adjustment of forces—or reciprocity if you vill—between the body functions, and between the external and internal parts; but above all between he mind and body [22]. This has ever been the ighest aim in the education of the young. And ow, in closing, permit me to quote the immortal vords of Aristotle as my motto: "*Nihil erit in ntellectu quod non antea fuerit in sensu.*"

The Value of Lectures.—Lectures depend entirely for their value upon the manner in which they are given. It is not the matter, nor the subject, so much as the man. —FARADAY.

International Congress.

THE ANTITUBERCULOUS CAMPAIGN IN LATIN AMERICA.*

BY ÉMILE R. CONI, M.D.,
BUENOS AYRES, S. A.

PRESIDENT OF THE PERMANENT INTERNATIONAL COMMISSION FOR THE PROPHYLAXIS OF TUBERCULOSIS IN LATIN AMERICA; CORRESPONDING MEMBER OF THE "INTERNATIONALES CENTRAL-BUREAU ZUR BEKAMPFUNG DER TUBERCULOSE" OF BERLIN; FOREIGN CORRESPONDING MEMBER OF "L'ACADÉMIE DE MÉDECINE" OF PARIS; DIRECTOR OF "LA LUCHA ANTITUBERCULOSA" AND OF THE ANTITUBERCULOUS DISPENSARIES OF BUENOS AYRES, ETC., ETC.

MR. PRESIDENT AND GENTLEMEN: I desire to thank most heartily the Committee on Organization for having chosen me as one of those to address this assembly. It has honored, in the person of an humble worker in medical science, South America; and in the name of my country, the Argentine Republic, I tender you the expression of our profound gratitude.

In January, 1901, the first Latin American Congress, which met in Santiago, the capital of Chile, formed a permanent international commission for the purpose of combating tuberculosis in Latin America, according to a plan submitted during its session. This assembly appointed me as the president of that commission.

In order to best fulfil its mission, it took for its model the Central Committee of Berlin, which pursues, with so much intelligence and perseverance, the same ends.

Inquiry showed that many South-American countries had undertaken such work some years previously, while others remained entirely inactive. Before taking up the task, it was necessary to ascertain the numerical importance of the common enemy, in order to form a plan of battle, and uniform method of action, to the end that the antituberculous crusade might attain the best possible results.

Investigation of statistics demonstrated to the permanent commission that tuberculosis prevailed extensively in Brazil, Chile, Peru, and Venezuela; to a lesser degree in the Argentine Republic, Uraguay, Paraguay, Colombia, Mexico, and San Salvador; and finally, that Bolivia and Ecquador were the most favored countries, tuberculosis being almost unknown in some of their centers of population.

As the campaign against tuberculosis now occupies the attention of the whole world, I thought it might be of interest to this learned assembly to know the progress and present state of the antituberculous campaign in the New World. I have therefore chosen this theme as the subject of my discourse.

The first resolution adopted by the permanent International Commission was to found a review which would serve the purposes of propaganda, make known the work of the commission, promote the formation of leagues in America, and bring about the harmonious relations which should exist among associations created with the same end in view.

The commission being without resources, the Argentine League against Tuberculosis offered it valuable aid in placing at its disposal the journal which was published under the name of *Review of Tuberculosis*, which name was later changed to *The Antituberculous War*.

The coöperation of this journal was of the greatest assistance to the international commission. Its propaganda has awakened from their apathy, the governments and American people, who realized

*Address delivered before the Fourteenth International Medical Congress, Madrid, April 23-30, 1903.

how criminal it was to remain indifferent to the terrible scourge.

To-day anti-tuberculous leagues exist in Brazil, the Argentine Republic, Chile, Uraguay, Paraguay, Bolivia, Ecquador, and Cuba; and others are planned or in process of formation, in Peru, Colombia, Venezuela, Mexico, San Salvador, and Costa Rica. The governments of the latter countries have interested themselves in this important question.

In Peru the government, on January 5, 1900, named a commission of eminent physicians, who were charged to "seek the causes of tuberculosis in the country, and study measures to combat it, or at least reduce, as far as possible, the ravages of the disease."

In Colombia the Academy of Medicine of Bogotá has approved a series of motions bearing upon the prophylaxis of tuberculosis, and there is every reason to believe that the civil war devastating that country has, alone, retarded the formation of a league.

The same is true of Venezuela. The *Gaceta Médica*, in publishing the health statistics of that country, has shown a considerable mortality from tuberculosis in Caracas, and consequent need of special measures.

Mexico, through its "Superior Counsel of Health," under the presidency of Dr. Licéaga, has been engaged in the anti-tuberculous war for some years. In order to render it more efficacious, the counsel is in hopes that the formation of a league may not be long delayed, that the laudable efforts of the people, governments, and municipalities, may be united.

San Salvador, Guatemala, Nicaragua, and Costa Rica have not wished to be out-distanced in the work. It suffices to glance over the medical publications of these republics, especially the first—San Salvador—to be convinced that their sanitary authorities are beginning to manifest a real interest in that which concerns tuberculosis.

As to the other countries in which leagues have already been formed, it may be stated that the Argentine Republic occupies the first rank in South America, and Cuba in Central America. The problem has been dealt with in both these countries in a very practical manner, through the creation of antituberculous dispensaries, sanatoriums, vacation colonies, seaside hospitals, and promotion of popular education through an active propaganda. Moreover, their authorities have issued decrees concerning prophylactic measures of the greatest importance.

Contrary to the conditions obtaining in Europe in relation to tuberculosis, where private initiative plays a large part, Latin America is obliged to depend almost exclusively upon public coöperation in its campaign against tuberculosis; the latter having, as it were, a semi-official character. The better classes have failed to respond to the appeal made to them, and, sad to relate, the medical world in general exhibits the greatest indifference to the noble but arduous task undertaken.

The present social organization in the countries of Latin America does not permit dependence upon support from the mutual aid societies, which might lend powerful assistance to the creation of public sanatoriums, replacing, to a certain extent, the immense advantages of the German insurance against disease and incapacity. Thus, in the New World, the establishment and support of sanatoriums constitutes a problem difficult of solution.

Brazil, Chile, Uraguay, Ecquador, Peru, and Cuba have planned, or have in course of construction, sanatoriums in localities which leave nothing to be desired. We wish them a long and successful existence, trusting that they may not be compelled to close their doors, as was the sanatorium of Porta-Cœli in Spain.

The Argentine Republic has, for two years, possessed a sanatorium in the province of Córdoba, to which the Argentine Parliament has granted a subsidy of 200,000 nationales (about 420,000 francs). This institution, which is well located, constructed according to modern ideas of hygiene and comfort, and compares favorably with the best German sanatoriums, is also hampered by lack of funds.

The Argentine League depends for its existence upon the National Congress, executive and municipal powers, and upon the unremitting labor of a few physicians who have consecrated their time to the work, much to the detriment of their own interests. These physicians believe it best to concentrate their attention upon the work of anti-tuberculous dispensaries, vacation colonies, seaside hospitals, etc., and propaganda which they consider the basis of success. To obtain the best results, the anti-tuberculous campaign should begin with instruction of the people concerning the disease. To this end it has put in operation various measures, such as public lectures, and instructions on circulating leaflets or published in the journals. Its work has been completed in obtaining the passage of a municipal decree embodying stringent measures for the prophylaxis of tuberculosis.

If Germany and France occupy the foremost rank in Europe as far as anti-tuberculous propaganda is concerned, three countries in Latin America also merit mention: The Argentine Republic, Brazil, and Mexico.

This assertion is borne out by the following facts:

The Argentine League has, in the fifteen months of its existence, distributed more than 600,000 pamphlets bearing upon anti-tuberculous education. It has extended its instructions concerning tuberculosis and alcoholism to the most remote sections of the Republic. Finally, it has promulgated useful prophylactic knowledge through printed instructions upon match-boxes. One of the members of the league, a municipal counsellor, in April, 1902, succeeded in having regulations issued concerning the prophylaxis of tuberculosis, the details of which are the most complete known, and they have received the merited honor of publication in the French, English, German, Italian, and Portuguese journals devoted to tuberculosis.

To keep the public mind aroused, the league has, since the first year of its existence, given a series of illustrated lectures, which have been largely attended Moreover, it has distributed each month thousands of copies of its journal, which keeps the public in touch with what is being done the world over to combat tuberculosis.

In Brazil the initiative in the work was taken by Dr. Clemente Ferreira of São-Paulo as early as 1898. He then outlined a plan for the purpose of combating tuberculosis through instruction in prophylaxis and the hygienic education of the people, as well as by the establishment of sanatoriums for indigent tuberculous patients. The Paulist Society of Public Sanatoriums was founded under the patronage of the Medical and Surgical Society, and constitutes in itself an anti-tuberculous league. Dr. Ferreira has published, in Portuguese, the interesting pamphlet by Dr. Knopf entitled "Tuberculosis as a Disease of the People, and Means of Combating It." In collaboration with Dr. V. Godinho, he edits the *Defense against Phthisis*, the official organ of the Paulist Association of Public Sanatoriums.

Other cities of Brazil which have followed the ex-

ample of São-Paulo are: Rio de Janeiro, Bahia, Pernambuco, Juiz de Foro, Curytiba, Campos, etc. The antituberculous leagues play an important part in popular education, which they promote through public lectures, printed instructions, etc. The Municipal Counsel of Rio de Janeiro, in 1901, issued regulations concerning the prophylaxis of tuberculosis which embrace measures of the greatest value. Thanks to the efforts of the Brazilian League, under the presidency of Dr. Azevedo Lima, to whom the campaign against tuberculosis in Rio de Janeiro owes so much, a dispensary was opened in that capital in 1902.

A municipal ordinance places pulmonary tuberculosis among the diseases of which a report is obligatory, as is disinfection in that condition.

As before stated, the Mexican Board of Health has set itself vigorously to work through the dissemination of instructions concerning tuberculous patients and their surroundings. A pamphlet entitled "Defense against Tuberculosis" has been widely distributed. The work of Dr. Knopf has been translated into Spanish, and, finally, a free bacteriological service for the gratuitous examination of sputum has been organized.

The Chilian League, having its headquarters in Santiago, was founded May 26, 1901. It has done some important work, and disseminates instructions through booklets, notices attached to walls, etc. At present it is occupied in the creation of a hospital and dispensary, the latter to open in the current year. At the Institute of Hygiene, the league has succeeded in establishing a bacteriological service for the gratuitous examination of sputum.

Unfortunately, attempts to form similar leagues in the other principal cities have failed. Reporting of tuberculous cases is obligatory in Santiago, though disinfection is not.

An antituberculous league was founded at Montevideo, the capitol of Uraguay, in July, 1902. It has given public lectures, distributed instructions concerning the prophylaxis of tuberculosis, and founded a ladies' society, which actively coöperates in the collection of funds. The first dispensary is now in operation in the quarters occupied by the league. The Institute of Hygiene offers gratuitous examination of sputum.

In Venezuela the Council of Hospital Administration distributes leaflets containing the precepts relating to tuberculosis, which are published by the Imperial Sanitary Institute of Berlin. Drs. Razetti and Herrera Vegas are engaged in the formation of a league, which no doubt has been retarded by the war of which that country has recently been the scene. In Peru Drs. Belisario Sosa and Rómulo Eyzaguirre propose to form a league also, after the report of the special committee named by the government has been published.

In Asuncion, the capital of Paraguay, an antituberculous league, having for its president Dr. Hector Velasquez, has been formed, and has already commenced work.

Dr. Valentin Abecia of the city of Sucre has organized committees in various parts of Bolivia, and presides over the Bolivian League, which has obtained from the National Congress the obligatory reporting of tuberculous cases and isolation of patients in hospitals.

The Superior Council of Health at San Salvador has also made reports of tuberculous cases obligatory and sanctioned a series of prophylactic measures relating to churches, schools, public institutions, etc.

In conclusion of this brief review, mention must be made of the Cuban League, which has published, since June, 1902, a monthly report of its work. It has created delegations to the interior of the island, and has caused the formation of a commission for the special study of questions pertaining to tuberculosis. The provisional government, desirous of establishing a sanatorium for tuberculous patients, submitted the project to the league. The committee named for this purpose has selected the property of Asuncion, which has been acquired by the government. Fernandez de Castro has ceded to the league, land at the mouth of the Jaruco river as a site for a hospital for the treatment of tuberculous children. The Cuban League has delivered many lectures, and established a dispensary in Havana in February, 1902.

The first antituberculous dispensary in Latin America was established in Rio de Janeiro, January 26, 1902, by the President of the Brazilian League, Dr. Azevedo Lima. The President of the Republic and the archbishop assisted at its inauguration.

The second was established in Havana in February, 1902, by the Cuban League against Tuberculosis.

Two others in Latin America are located in Buenos Ayres. The first was thrown open to the public on July 1, 1902, the second in September of the same year. In the organization of these dispensaries, the German Polyclinic of Fränkel and the French and German dispensaries were taken as models. At present a model dispensary is in course of construction.

The scientific direction of these two Argentine dispensaries, which give daily assistance to 150 indigent tuberculous patients, being under my charge, I deem it of interest to make known the excellent results which we have attained, despite the short time they have been open.

We give to the tuberculous poor coming to our dispensaries the most complete protection and assistance, treatment and medicines, bed and body linen, sputum cups for the pocket, as well as for the home, and they are supplied daily with two liters of pasteurized milk, a half kilogram of bread, and 750 grams of beef or mutton. At the patient's first visit, he is given the requisite instruction concerning his disease.

After having been examined by the physician, he is given a card of admission, his sputum is submitted to bacteriological examination, and the following day an inspector visits his home and reports upon the hygienic conditions, poverty of the family, and takes steps toward remedying the latter.

The patient is authorized to send daily to the dispensary for what he needs; his card of admission sufficing for this purpose. Under penalty of deprivation of assistance, for the first offence, and erasure of their names from the register for the second, they are required to carry with them always the sputum cup, as well as to follow strictly the verbal or written instructions given them by the physicians or inspectors.

The weight of the patient, taken every two weeks, is inscribed in the register, as are also his clinical history, and the periodical examinations of his sputum. If the patient cannot leave his home (in cases of fever, hæmoptysis, prostration, etc.), a notice sent to the dispensary procures him attendance at the house.

Inspectors are required to visit patients in their homes once a week and report their observations to the director. Every two weeks they hand in a written report of the results of their visits. If the patient has no one to care for him, or his condition demands it, he is removed to the hospital.

Registered patients are required to present them-

selves at the dispensary once a week, in order that their progress may be watched. After having received their daily alimentary ration, they may consult the physician, receive hypodermic injections if necessary, and before leaving, obtain remedies from the dispensary drug room.

Those patients in whom the disease is far advanced, pregnant women, and those suffering from digestive disturbances, are entitled to a larger quantity of milk.

Excessive indulgence in alcohol is strictly prohibited, under penalty of withdrawal of assistance.

Our experience in these two dispensaries has been that the patients soon show decided improvement. A gain in weight is often seen, the appetite increases, and through the improvement in the general condition, the patient gains renewed strength and is able to resume his work.

Germany has been able to combat tuberculosis in sanatoriums by reason of the large sums derived from insurance societies. In Latin America the situation is quite different. As I said before, the antituberculous campaign cannot count much upon private beneficence, but must depend largely upon public support. The resources of the Mutual Aid Societies are as yet insufficient for the maintenance of sanatoriums. We must, therefore, depend upon dispensaries, which stand for prophylaxis,assistance in the home, and the hygienic education of families.

The dispensary, it is true, cannot replace the sanatorium as the sole factor in the treatment of tuberculosis. It must, therefore, be considered as the means through which may be extended to the greatest number of poor patients the benefits of medical and material aid to meet the most pressing needs; and it represents a valuable source of popular education and tuberculous propaganda.

The dispensary, by reason of the benefits it offers, attracts a large number of tuberculous patients, and consequently many recent cases are discovered.

It cures, economically, many patients, relieves a large number, and gives moral support and comfort, even to those whom death claims, sparing them the sorrow of breathing their last sigh in a hospital, by making family surroundings possible through the material aid which it offers.

It has the advantage over the sanatorium that it watches over those who are threatened with the disease, gives care to the incurables not admitted to hospitals and sanatoriums, according them treatment which relieves their sufferings and the necessary instruction through which they avoid contamination of their neighbors.

The dispensary may also serve for the selection of patients suitable for sanatoriums, and for the control of those who need home care and the assistance which is almost indispensable to the majority of those dismissed from the sanatoriums. Finally, it serves to combat alcoholism, unwholesome habitations, and overcrowding; and constitutes a veritable school of hygiene.

This communication, gentlemen, has had for its sole object, to show you how we of the New World try to put in practice the teachings of progressive Europe in all that concerns that most transcendental question, the warfare against the modern pest.

Mastoiditis Due to the Gonococcus.—C. Trow reports the case of a man of twenty-two years who denied ever having had gonorrhœa, but who developed a mastoid inflammation following a purulent otitis. Operation was done in the usual manner, and the wound healed without incident. Examination of the pus from the ear showed typical gonococci.—*Canadian Practitioner and Review*

THE EXPANSION OF A SPECIALTY.*

By HOWARD A. KELLY, M.D.,
BALTIMORE, MD.

The history of medicine, as I contemplate its course, brings to my mind a vivid picture of the river Grand in America, a river which has its remote origin in thousands of brooklets and streams, and then in mighty lakes formed by their union. Leaving the wide expanse of Lake Erie, the silent flood continues its slow majestic course, moving onward with all the gathered forces of the many waters behind until it reaches the mighty precipice of Niagara. Over this it plunges 160 feet, in a vast cataract, rushing, whirling, and boiling onward to Lake Ontario, not many miles away.

Even so is it in the life of the medical body politic. For, if we except the barren periods during which wars have from time to time stirred individual countries, the history of mankind in all its phases has been none other than this: A broad stream, taking its rise in countless sources, advancing by slow increment from century to century, for years upon years seeming scarcely to move; then suddenly, in a period measured only by a single life, with a few discoveries come, in rapid succession, changes greater than those of all the previous ages, and we find ourselves standing in the midst of a rushing torrent, swifter than any ever yet noted in the world's history, about to be swept—we know not whither.

So wide-reaching are these recent changes in the medical world that it seems well-nigh impossible for those of us now living in their midst to form any adequate conception of the force of the new impulses which have been communicated to our art, or to conjecture the goal toward which we are being hurried. The one great principle governing the spirit of the times in which we live, is that of decentralization and diffusion, replacing segregation and separation. By means of these new forces the hamlet, the village, and the little town no longer exist, but have become part and parcel of the nearest great city. Even more, the city itself, in a sense, no longer exists, and humanity has become an organized unit. With this great transformation has come *pari passu* the rapid diffusion of knowledge, through which every man in the civilized world has suddenly become neighbor to every other man. The change in the face of the body politic is no less seen in its component parts. And where do we find a more striking example of these new ties of brotherhood than in the bonds which now unite us, practitioners of the healing art the world over, into a union made manifest by the community of interest and of aim distinguishing men who, regardless of worldly considerations, combine in devoting their time and their talents to relieving the sufferings of the human race. A noble calling if rightly exercised in a spirit of self-sacrifice without fear or favor of man.

The time was when this principle of diffusion was manifested by a few great lights of our profession, who delighted in peripatetic wanderings, adorning, it might be, one after another, the chairs of the great Italian, Swiss, Dutch, or French universities; when the peripatetic surgeon toiled over rough and dangerous highways from city to city, everywhere consulted, and every where distributing the benefits of his skill. This ancient practice, which I think has scarcely received its due consideration at the hands of the medical historian, has continued down the centuries, even

*Address delivered before the Fourteenth International Medical Congress, Madrid, April 23-30, 1903.

as far as one of my own immediate predecessors in Philadelphia, the well-known ovariotomist, Washington L. Atlee, who was wont to take long journeys, travelling from town to town performing his hazardous operations.

Now, what a change! Once more, like the great lights of our profession in the past, we have become peripatetic, and the multitudes share what was once the privilege of a favored few. And what more fitting place could be found to celebrate this new activity than Spain and her capital, Madrid, the ancient land and early home of civilization and learning, which have boasted the names of such fathers in medicine as those who flourished in the reigns of the Emperor Charles the Fifth and of King Philip the Second. I refer to Francisco Lopez of Villalobos, to Andreas a Laguno, Christobel da Vega, Louis Mercado of Valladolid, Francisco Diaz, and to Nicolas Boccangelino, the great writer on the plague, as well as a host of others, including Fragoso and Charcon and Arcea. Would that such unity prevailed among those who practise law! Would that such harmony were the rule in the religious world!

The peripatetic tendency of the profession which has brought so many of us to share the generous hospitality of this great capital to-day, has been the responsible efficient agent in bringing about a condition of culture and an elevated status in the healing art never yet witnessed, nor even anticipated in the history of the world. I would that my powers were equal to a recital of the numerous blessings thus accruing to humanity, blessings which, I fear, can be only faintly conjectured. I must not, however, pass over so great a subject without emphasizing a few of these benefits; let me, therefore, cite some encouraging facts from my own country, with which many of you here present may not be familiar. In America, as you are perhaps aware, the standard of medical education has for many years been extremely low, owing to the multiplication of medical colleges. But of recent years, in my journeys from place to place, and in my intercourse with the many physicians who visit my clinics, I have everywhere discerned a marked improvement; and during the last twenty years the advance has been so rapid that even our smallest towns can to-day show some of the best surgery of the New World. Everywhere throughout North America, men are pouring into the clinics attached to large hospitals in order to improve their knowledge and technique, while others, as you know, are crossing the Atlantic in thousands to train themselves to do better work at home.

Transportation facilities are primarily responsible for this diffusion of learning, but another quickening impulse has entered as a significant factor into the medical culture of communities at a distance from the more noted seats of learning, and that is the establishment of small hospitals, both public and private, in towns and villages over our entire continent. These little hospitals are the living forces destined to transform American medicine and surgery, for they act as a continual stimulus to the men in charge, thus creating, sooner or later, an honorable rivalry wherever they exist, and they afford a constant and convenient field for accurate clinical observation, never found in centuries of private practice. In the women who enter them to study nursing we find a system of well-trained intermediaries between the medical profession and the public. With such coadjutors always at hand, the profession comes into touch with the laity, the people are instructed, and the whole sanitary life of the body politic, being quickened, enters new channels of life and growth. The public, which enjoys the blessing of such ministrations, then becomes interested, and as soon as the reasonableness of our aims is perceived, gifts are forthcoming, by means of which thousands of patients are sought out and benefited whose needs would never otherwise have come to light. These beneficial results are not the only outcome of the small private hospital system. The small hospital serves as well as an educational center for the surrounding professional community, each one of them attracting within its precincts the little army of practitioners scattered about in its vicinity, who never find it possible to leave home after their student days are over. The practical benefits of the object lessons thus given so near at hand are self-evident at once in the cases which begin to flow steadily in from remote places, representing patients who have neither the means nor the inclination to seek the distant large city. After a few years of education given in this practical fashion, the usefulness of these small hospitals becomes yet more evident in the changed character of the cases brought in for treatment. No longer do they come, as at first, in a desperate, and often hopeless condition; on the contrary, they now appear in the early stages of illness, nay, even on the suspicion of grave disease, if a consultation is thought advisable. In surgery, which forms the larger and more conspicuous part of the small hospital's work, I can think of no more ready and notable example of the improvement wrought than appendicitis. At first the surgeon of the small hospital, who had grown to be the consultant over a wide neighborhood, was only called in to see appendicitis cases when general peritonitis had ensued, or after the formation of a large abscess, when the case was often hopeless; but after a few years' teaching through his hospital clinics, his *clientèle* of country practitioners have become just as keen as their city colleagues in recognizing the significance of right iliac pain, and as a result the surgeon is at once called for and many lives are saved. I well remember a fervid oration by one country practitioner, who had become so impressed with the importance of early operation in appendicitis that he dramatically exclaimed: "if he himself ever had the disease, and did not have sense enough to demand an immediate operation, he wanted his medical friends to *down* him and do it," *vi et armis*. It must ever appeal to the surgeon who loves his art, as a subject for regretful consideration that his individual skill can reach so few of those who suffer; how heartily then ought he to rejoice at this multiplication of well-trained minds and skilful hands. Of all the unheralded silent influences working out from the medical profession for the benefit of suffering humanity, I reckon the small hospital as perhaps the most potent. Who, a generation ago, could have anticipated such a blessing? Yet to-day we find it ever expanding and spreading its beneficent aid farther and farther. Shall we not pause a moment and express our profound sense of thankfulness for the gift?

But changes are now taking place on all sides. The rapid acquisition and diffusion of knowledge that characterize the day in which we live, are like a swirling current engulfing the old ideas and dissolving them, only to deposit them again recrystallized in forms so entirely new that their bare presentation in the journals of to-day would often be more unintelligible than an abstruse language to our colleagues of a generation ago.

It is my desire now to discuss more particularly of the great changes that have taken place in my own line of work, which lies in part in those diseases peculiar to women; I propose to look briefly at the past out of which gynecology has

grown; to consider her present relations to medicine and to general surgery; and then to hazard a prophecy regarding her future. I do this in the hope that by thus discovering and correctly interpreting the natural tendencies of gynecological surgery I may exert a far-reaching influence. For such a body as I now address represents a temporary established brain of the medical world, which, if now impressed, will, in its process of disintegration, diffuse motor impulses, to be carried by the different members into distant lands and thus promote the natural evolution of the great domain of surgery.

I shall first try to bring before your minds a familiar historical picture, reminding you that gynecology is only of recent growth, being but an offshoot from the extensive and confused domain of general medicine somewhere about half a century ago. I shall then try to demonstrate that its domain as a specialty was at first but a narrow one, beginning with small issues and then shooting up in a marvellous manner to its present proportions under the wise hands of its master builders, many of them our immediate predecessors, some of whom are still living and honored among us to-day. Along with this demonstration goes the corollary, which I trust you will be prepared to admit, that a still further expansion of the gynecological field was natural and advisable. It is an indisputable fact that gynecology has grown to cover a wider territory; the question now before us is: Has gynecology ceased to grow territorially? Lastly, having, I hope, prepared you to accept my interpretation of the signs of the day, I shall urge upon you that the best interests of gynecology lie in the direction of a *rapprochement* with general surgery.

My subject is manifestly too broad for a detailed consideration, but I trust it will be possible for me to impart my convictions by briefly referring to facts which come within the cognizance of every medical man acquainted with history.

Any real growth in the art of medicine has ever been the product of two factors: on the one hand, a healthy philosophical speculation, controlled on the other by scientific observation at the bedside and the autopsy, aided by experiment. The great medical man of bygone centuries was essentially a philosopher, a man of greater calibre than most of his successors, but a regard for the facts which might have formed a substantial basis for his science was lost in the vagueness of his uncontrolled speculation. I think, for example, in this connection of the remarkable work of the Jesuit, Athanasius Kircher, on the Pest, and of the philosophical Bartholinus, of the great Bauhin family. I cannot help commenting in passing on the fact that we have now passed to the other extreme, for there exists to-day a notable lack of the speculative quality in our profession, the whole tendency of the age being pragmatic. Ehrlich's philosophical speculations concerning immunity and its relations to the formation of antibodies in the organism as a reactive response to the presence of certain albuminoid atom complexes, forms a notable exception, which draws attention all the more urgently to the lack of the speculative quality in modern medical literature.

As soon as scientific observation began to ally itself as a necessary co-worker in the development of medicine, the transformation was so widespread and so deep that a host of specialties was created, many of which, under the unifying effect of further discovery must tend inevitably to return to the general. Let me illustrate what I mean by evolution out of the general through a process of specialization followed by a return to the general. Take, for an example, those subjects which for the past decade have so occupied the medical horizon: the plague, malaria, and yellow fever; three of the greatest curses of our race. What volumes have been written upon these ancient foes, what labor has been spent in investigation, and with what self-sacrifice, and noble effort have a small body of scientists in Germany, France, England, and America devoted themselves to their extermination! At one time it seemed as if the whole world might be condemned to take toxins to ward off these pests, and that the great boon to humanity conferred by special researches was to be some potent poison, derived through the organisms themselves as intermediaries, which, when injected into the plague-stricken victims would save a large percentage of lives. And what has proved to be the source of evil? The rat, the flea, the fly, the mosquito! The answer to the problem is so simple that the whole question of immunity has been transferred again from the laboratory of the specialist to the field of the general practitioner, who is now able, with the assistance of the new light, to cope with these foes. The thought stirs me in passing that we have scarcely yet paused long enough to be truly grateful for benefits such as we have received. In my own country, we are now finding it difficult to secure adequate recognition of the services of the man who has wiped out the curse of yellow fever and saved millions of lives, without speaking of money. I refer to my late distinguished friend and colleague, Dr. Walter Reed.

The rootlets of gynecology everywhere interpenetrate our ancient medical literature from the Coan and from the Alexandrian schools downward; but in spite of the writings of Soranus, and the faithful transmission of his observations through the Greek down across the barren fields of the Arabic writers of the middle ages, there was still no gynecology in the true sense of the word. Hope first began to dawn when Versalius' great "Anatomy" appeared in 1545, and was quickened by scattered observations in the works of the great Paré and of Plater, together with the appearance of the pseudo-gynecologies of the sixteenth century edited by Caspar Wolf, Caspar Bauhin, and Israel Spach, those "*Gyneciorum libri de affectibus parientium et puerperarium, etc.,*" into whose pages we all look from time to time with such deep interest. In the works of Luis Mercado, the great Spanish physician of the sixteenth century, there is a precious little reference which cherishes our hopes; while speaking of fistulas of the womb he paints for the first time a vivid picture of the distressing effects of a vesico-vaginal fistula. I cannot let this occasion pass without congratulating our hosts upon the acute powers of observation displayed by their great predecessor. He remarks regarding the fistula: "*Verum quia aerumnosam calamitosamque vitam et multis periculis obnoxiam hujusmodi affectiones accersunt: siquidem ad intestina et ad vesicam adeo profunde aliquando permeant, ut urina et alvi excrementa per fistulam facile instillent, etc.*" But the fruition of the hope was not yet to be, and three centuries had still to elapse before the clear light broke upon the field which to-day is the common property of every surgeon. Time fails me, or I would gladly pause here to follow the example set by Louis Deroubaix of Brussels and trace the history of vesico-vaginal fistula, using this as an admirable means of developing the history of the gynecological specialty at large. I must content myself, however, by indicating on broader lines that gynecology did not, as might be supposed, begin after the manner of obstetrics as a specialty already established in

the hands of women. The practice of obstetrics was gradually transferred to the hands of men after the appearance of that quaint little book the "Hebammen Rosengarten" of Eucharius Rhodion, in 1513, followed by Paré's introduction of the principle of version, and the labors of his pupil Jacques Guillemeau in the same field, together with Rousset's work on "Hysterotomotoky." From these beginnings the obstetric edifice grew slowly toward completion during the next 150 years, under the united efforts of a host of great men, whose names I must not even pause to recall. The evolution of gynecology took place under other auspices. First established on the unstable foundations of Hippocratic teaching, it continued to grow under such occasional incidental increment as accumulated during the sixteenth, seventeenth, and eighteenth centuries. It remained entirely destitute of any scientific basis until the first half of the last century, when there arose a mushroom growth of pseudo-specialists, who frittered away their time and talents in the development and exercise of gynecological *fads*, which have not yet altogether passed away. I do not know whether the fair name of our specialty has suffered more from these fads in England and in my own country than elsewhere, but certain it is that there still exists among us a number of men, the acme of whose gynecology consists in discovering a little rent in the perineum, or a laceration or ulceration of the cervix. I have only lately received a letter of reproach for not sewing up a small tear in the neck of the womb which was to have the effect of curing a dangerous menorrhagia. The old régime is about passing away, and with it those whose whole science consists in finding and correcting a flexion, often an anteflexion, with a uterine sound or a lever, and then adapting a pessary. The man who runs to a fad will, however, always remain with us, and in these days he removes the ovaries for pelvic pain and for dysmenorrhœa, he does hysterectomies without number, and I am almost inclined to class with him my friend who desires to operate on every woman who has a fibroid tumor.

I spent some of the wasted months of my young life in a dispensary conducted on these principles, where we learned, without rhyme or reason, to paint the vault of the vagina with iodine, to pack the vagina with a glycerin tampon, and to prescribe daily prolonged hot vaginal douches. I will not be ungracious enough to mention any of the names of this group of gynecologists, for they lived among our immediate predecessors, and whatever we may think of their practice, we associated with them at our meetings and loved them individually too well to recall their memories with sentiments other than those of strong personal affection. And who of us now living, had our lot been cast with those days, would have done better?

There was no hope of advance for gynecology on such lines, and I have no doubt many a young recruit felt as I did myself, somewhat ashamed when he cast his lot for life into her lap. It was when matters were in these straits that hope received an impetus from two new and unexpected quarters: Two little streams appeared, one rising in 1809, in the hills of Kentucky, at the doorstep of Ephraim McDowell, honored the world over as the first ovariotomist; the other springing from the fertile genius of Marion Sims, of Simon, and of Jobert de Lamballe, the great pioneers in plastic surgery. These rivulets, speedily nourished from other rich sources in France, in Germany, and in England, rapidly swelled in one single generation into the mighty streams of abdominal and vaginal surgery, which, uniting together to-day, constitute the broad expanse of scientific gynecology.

Following these two lines of development, gynecology has opened up to successful cultivation on the one hand the entire field of abdominal surgery, which, therefore, belongs to her by right of conquest and eminent domain; while on the other she has shown the world the most successful and delicate plastic surgery as yet seen. The specialty as it exists to-day, is the outgrowth of incessant laborious cultivation, each step forward being controlled by thorough scientific investigation, by rigorous pathological study, and by accurate clinical observation. In the words of one of our greatest leaders, the eminent son of a distinguished father, who was himself a gynecologist: "*Wenn einer medicinischen Disciplin die pathologisch-anatomischen Methoden als Ergänzung sorgfältiger klinischer Beobachtungen und experimenteller Untersuchungen förderlich gewesen sind so kann man das zweifellos von der Gynäkologie sagen.*"

Let us now glance briefly over the achievements of gynecological surgery up to the point where she at present stands. From such a vantage ground, we shall, I think, be better able to estimate those things which are still to be done, and it may be to peer through the mists obscuring that which lies hidden in the womb of the future. Weigh well these gains as I name them, and do not tell me the truths they represent are trite. I shall be sorry for my profession if the day ever comes, when we, crying for somethink new, turn wearily from the considerations of our most precious possessions, because they are a decade or two old.

First of all, to the glory of Germany, England, and France, which have produced a Pasteur, a Koch, and a Lister, we have now a clear conception of the whole realm of microorganisms in their relations to infectious diseases and to surgical infection; and, as a result of this revelation, we have rapidly worked out efficient means by which the mortality of such an operation as ovariotomy has been reduced within a few years, from 50 to 25, to 5 per cent. or less. As a corollary to this discovery has come the disinfection of everything within the range of the field of operation, including the disinfection of the hands or their protection by gloves. Methods of dealing with pelvic inflammatory disease have been clearly established. The function of the peritoneum and the principle of its drainage are at length really understood. The treatment of uterine flexions is on a fairly settled basis. The great field of hernia is satisfactorily cleared up. Appendicitis has been plainly defined as a surgical disease and is treated as such. The technique of resection and anastomosis of the intestine, from being one of the most dangerous has become one of the safest operations. The whole realm of urinary infections is now accessible to diagnosis and treatment. Pause here for a moment to think what has been done in discovering the relative frequency and the proper methods of treating extrauterine pregnancy, of tuberculosis, and of carcinoma of the uterus; and note also what an achievement are the hysterectomies and myomectomies for fibroid uterine tumors. All these burning questions of a generation ago have been resolved by the labors of my colleagues in Germany, in Russia, in France, in England, and in America. Did time permit, what a galaxy of noble names I might here recount, each one of which would call forth resounding cheers! But I must pass on, and rather than make invidious distinctions among the great men of the past by recalling the names of a few, I will leave each one of

you to conjure up for himself the list of those he most delights to honor.

What now remains to be done? In my opinion, surgical possibilities in the gynecological field are almost exhausted, and the quickening revelations of sepsis and asepsis have been pushed almost to their limits. The really great and purning questions of the day are: Immunity and the causation of cancer; but these are matters relating to the broad domains of both medicine and surgery, not to the gynecological field alone.

Within the lifetime of some who are here present, and almost under the eyes of those who may still reckon themselves young men, scientific gynecology has grown up, and one after another its great questions have been met and answered, until, to-day, the few perplexing problems which still remain to be solved are largely identical with those that confront the entire surgical world. The distinctive mark of gynecology, that which has stamped it as a specialty *par excellence*, that which has elevated a body of workers in a special field to a commanding influence in the realm of surgery, and enabled them to take the initiative in many of the most important advances in that art, as well as to direct its thoughts into new channels, is the fact that here, in the female pelvis, thirty years ago, lay an unexplored surgical microcosm, and by addressing themselves assiduously to its particular problems, questions of the highest moment to surgery at large were to be solved. Thus year after year, in the great special journals, the *Archives*, the *Zeitschrift*, the *Centralblatt*, the *Annals*, the *Annali*, the *British Gynecological Journal*, the *American Journal of Obstetrics and Gynecology*, those storehouses of gynecological truth, discoveries rained down almost faster than we could appreciate them. But now the rain has ceased, or there remains at most only a gentle distillation of dew, and we may well cast about and ask once more: What new work is there for us to do? On what ground do we stand in our relationship to the whole domain of surgery? Are we, as heretofore, to remain specialists cultivating our own little corner of anatomy and pathology; or have we before us the prospect of more varied discoveries in a wider domain? And lastly, is a *rapprochement* in our relations to the field at large desirable? This uncertainty in regard to our future relations with general surgery is not confined to ourselves; our surgical colleagues may well inquire of us: Now that you have so clearly simplified the technique that it differs from our own field of activity in no essential particular, may we not safely and creditably adopt your methods and have a common part in your work?

Before attempting the answers to these questions touching our relations to the field of general surgery, let me speak briefly of the relations existing between gynecology and obstetrics on the one hand, and gynecology and general medicine on the other.

The most formidable hindrance to progressive change in the scope of gynecology would be its permanent *liason* with obstetrics; indeed the time is now come when the association which in their early days existed between the two has been discontinued in the interests of both. The relation of the gynecologist to the obstetrician has been a natural evolution. The earliest gynecologists were naturally obstetricians to whom their patients returned when they suffered from any pelvic ailments following confinement, or when they desired to ascertain why they did not become pregnant. Later on, when gynecology as well as obstetrics had become a science, the two fields of work still remained in the hands of one man, but he, as a rule, cultivated one at the expense of the other, a process of divergence between the two being thus established. I believe that Germany alone has shown the world a group of men equally great in both specialities. In other countries the tendency for men to devote themselves to one or the other exclusively has gradually increased, until to-day, with the exception of a few distinguished names in my own country, the divorce has been complete for many years. The reason for this lies close at hand in the natural incompatibility of a large private practice with gynecology. No gynecologist can afford to risk nights of uncertain rest and frequent broken engagements in order to practice obstetrics. I take it, it will always be impossible to effect a reunion between the two, but it would be, as I have already said, a serious injury to the future of gynecology should any unexpected turn of events result in their renewed association.

It is, on the other hand, hardly less essential to the best interests of gynecology that her relations with general medicine should become closer and more sympathetic than we find them to-day. It is not two generations since the specialist in diseases of women was preëminently a medical man, but with the advent of that great English star in the surgical world, Lawson Tait, the medical gynecologist sank into comparative insignificance. The severance of gynecology from general medicine has now become so complete, that it operates to the serious disadvantage of both, as well as to the detriment of many patients. There is noticeable at times a slight mutual distrust between the two branches of the profession; the medical man complains that the gynecologist is too often ready to operate without sufficient indication, and that the results of his handiwork are sometimes disastrous, while the gynecologist feels equally sure that his colleague frequently detains patients "under observation" for protracted periods, when the existence of some gross lesion demands immediate treatment. If I may take my own personal experience as a guide, both sides are unquestionably at fault. The average gynecologist must have a broader knowledge of general medicine in order to appreciate correctly the relations his local problems bear to the whole; the medical man needs, at some point in his training, to be brought into close contact with the work of a successful gynecologist, and, above all, he must learn to make pelvic examinations, and must not shirk this necessary diagnostic measure, as so many, unfortunately, do. I find, for my own part, the utmost benefit to myself, as well as to my patients, from the constant association with me in all my private work of a skilled medical man who has had such training as I have indicated.

My thought for my colleague is no new one; it is as old as Socrates, whom Plato quotes in his Charmides as saying: "And this is the reason why the cure of many diseases is unknown to the physicians of Hellas, because they are ignorant of the whole, which ought to be studied also; for the part can never be well unless the whole is well."*

Let us return now to the chief subject of our consideration, the future relation of gynecology to general surgery. The professional relationships at present existing between the gynecologist and his surgical confrère are most delicate and difficult of adjustment, nevertheless they control the future of gynecology, and to them I would briefly address myself in conclusion.

In other specialties, as for instance, eye surgery and diseases of the skin, we find a certain easily definable territory, possessing anatomical, patho-

*"Socrates in the Charmides of Plato," translated by B. Jowett, Vol. I, p. 11.

logical, and therapeutic peculiarities. Here, by common consent, the entire profession throughout the world has agreed to recognize fields of work detached from medicine and general surgery at large. But when we examine the gynecological field, we find that the distinctive marks of a specialty, which characterized it fifty years ago, under other conditions, have one after another disappeared. At one time there was a definite borderland (the "*Grenzgebiet*" of our day) between general surgery and gynecology, but to-day the line of demarcation has diffused itself widely, extending up into the abdomen as high as the diaphragm, as well as down to the pelvic floor, so that its boundaries are no longer recognizable. We must not follow our natural inclination and decide this important matter from the narrow standpoint of personal association and individual custom; rather let us take into consideration the evolution of gynecology in all parts of the surgical world, and then we shall perhaps be able to estimate the ultimate outcome of our specialty.

I trust that in my brief exposition, I have been able to show that, although there exists a historical continuity in the use of the term gynecology, the men who inherit the term differ *toto cælo*, and would never be recognized by their predecessors, were they suddenly to come back into their midst, as fellow specialists. So that what was gynecology yesterday is no longer gynecology to-day, and this change is not the result of an evolution by natural development from matrix to bud, and bud to flower, such as we have witnessed in the field of general surgery; on the contrary, it is, as we have seen, a complete transformation by which a simple little specialty of topical applications and petty operations in one field (vaginal) has been transformed into a specialty of difficult and dangerous abdominal operations.

It is an impossibility to fix precise limits for the gynecological field from historical data; and it is no less impossible at the present time to secure a consensus of opinion either of gynecological surgeons or of general surgeons as to what is included in the term gynecology. In other words, we here encounter an anomaly, found in no other true specialty; a name applied to a certain area in the center of a field, while the boundary of the field is undefinable. My German colleagues alone are prepared to give me a clear definition of the limits of the gynecological field, outlined by the boundaries of the female pelvis; but even among them I begin to note signs of dissatisfaction with the restrictions thus imposed on a specialty cultivated by men of extraordinary ability, who as surgeons are capable of extending their beneficent work to a larger field than custom and accident have assigned them. I take it, my German colleagues, especially those outside of the universities, will not always remain satisfied with the ill-mated association of gynecology and obstetrics. In France I find no such distinction, the gynecologists there, almost without exception, are surgeons in the broadest sense of the word, and for this reason the breadth of grasp upon their specialty shown by our Gallic colleagues excites the admiration of the entire surgical world. In England and America, ever closely united in matters medical by a common heritage, the utmost diversity of opinion prevails, but not without injurious friction. The gynecologist constantly seeks a wider and yet wider realm, while the general surgeon, forgetful of the lessons of history, seeks to restrict his colleague's activities to the particular area in which he, the general surgeon, found the gynecologist working during his own student days. On the other hand, the gynecologist is not without substantial ground for complaint in that he finds his practice being absorbed by his confrère, who no longer limits himself to his own extensive field, but does gynecology as well.

Why should we make any attempt whatever to adjust these national and local differences?

For two cogent reasons: In the first place, because it is a matter of no little moment to minimize the friction which at present disturbs the fraternal harmony of the profession, friction which inevitably delays progress and results in the loss of many lives. In the second place, because we of the medical profession are, as I have intimated, the only true cosmopolites of the world. No other profession and no trade can lay claim to such entire independence of national boundaries, nor does any other body of men have, like ourselves, for its sole aim the relief of those who appeal for sympathy and aid in their hour of distress, irrespective of nation and color. We alone, linked by true bonds of union, form an unbroken chain extending throughout all lands regardless of creeds and politics. We have ever been united by uniformity of practice, and united we must continue to be; therefore, if a timely word will assist in regulating these little differences, let that word be spoken and the adjustment hastened.

To this end I would urge for the present need, on the one hand, a thorough surgical training for the gynecological surgeon. He ought never, as in the crude past, to rise immediately from the ranks of men in general practice; on the contrary, he should first graduate well equipped in the broad field of general surgery. Only after such a training can he become a first-class specialist, but such a training removes his previous disabilities and fits him for the entire field of abdominal surgery, and under these circumstances any artificial boundary becomes an absurdity. Let the entire abdomen then be regarded as the province of the gynecologist. For the general surgeon, I would urge that he be accorded the full freedom of the pelvis to operate when he is so inclined, and that the general surgeon and the abdominal surgeon act in a spirit of generous rivalry. I am aware that such a radical proposition will not meet with immediate favor; I urge it, however, upon your consideration, for I am firmly persuaded that it will come with time, and it will certainly come with less friction, if we are prepared for the change, and ready to welcome it when it appears.

A gynecologist such as I have described would confine himself to the abdominal cavity by preference, since it offers a field sufficiently large for the exercise of his judgment and his surgical skill. He would be a specialist by predilection and by courtesy, in forcible contrast to the gynecologist of to-day, who is too often a specialist—in the narrow sense of the term—by necessity, because he has not the requisite training to occupy the broader field, which, nevertheless, he sometimes invades with disastrous results.

I claim finally that my proposition is reasonable, because of the unity which underlies the principles of all abdominal surgery. The term gynecology is to-day as much a misnomer and as meaningless as the analogous term andrology; in its narrow sense, it simply does not exist.

Congenital Single (Unsymmetrical) Kidney.—Ramón Guitéras reports three cases, and remarks that we can never tell by the shape, size, or appearance of a kidney whether it is single or not, and that we should never operate to remove a kidney without first catheterizing the ureter.—*Gaillard's Medical Journal.*

OUR CABLED REPORT OF THE INTERNATIONAL MEDICAL CONGRESS AT MADRID.

THE Fourteenth International Congress of Medicine, which met during the past week in Madrid, and of which we present a full and special cable report in this issue, was in many respects a notable one, especially on account of the importance and variety of subjects discussed. It was also of a sufficiently representative character to give authority and force to the opinions expressed on the various topics connected with international medicine in its broadest and most comprehensive sense. The subjects were well selected and, in most respects, were exhaustively treated by experts in different lines.

The prevention and cure of tuberculosis was, as might have been expected, a topic of leading interest, and its discussion tended to prove the great value of those fundamental principles of hygiene that apply to disease prevention in general and to that one in particular. Agreement on such points serves the purpose of generalizing methods which are far more important than any special form of treatment that must be necessarily limited in its application. With a universal disease, such as the one under consideration, it is rational and logical to expect that the remedy should be within the easy reach of all. As no amount of argument or discussion can give a different complexion to the necessities of the situation, it naturally follows that the more the truth is ventilated, the firmer will these fundamental principles of prevention and cure be established.

It is an encouraging sign of progress that cosmopolitan medicine rises to the occasion with a correspondingly broad view of present requirements. The program for sectional work was seemingly quite effectively carried out, although some of the plans, as first announced, were necessarily modified or altered to suit certain exigencies. The time allotted to subjects was necessarily limited, but was evidently well improved.

Unlike some previous congresses, there was no sensational elements in its proceedings calculated to astonish the scientific world by the announcement of some startling discovery, or of the adoption of some new doctrine of disease. The germ of cancer, for instance, is still undiscovered, and the treatment of the disease is still along the same old lines. The various serums that have been announced from time to time by the secular press have failed to establish their claims as curative agents, and while the contemplation of this fact may have its disappointing and melancholy aspect it is highly beneficial in the long run to know the truth as it is, rather than waste effort in the futile endeavor of following wrong trails.

The question of food adulteration was one of international importance and claimed a wide interest and becomingly earnest attention.

As there is no scientific excuse for counterfeiting foods in any form, the discussion bore upon the necessity of enacting practical laws against such frauds—an exceedingly difficult undertaking in view of the formidable antagonism of trade interests.

The necessity for unifying pharmacopœial methods for the preparations of medicaments was one that appealed to all as of prime importance, and its discussion was eminently proper before an international congress. Efforts in such directions tend to universalize science, to give it a truly international interest and aspect, and to bring all investigators into closer and more intimate contact. If we are ever to have a universal pharmacœpia, it must be made possible through such international agencies as these.

It is with no small satisfaction that we are enabled to place before our readers not only the principal addresses delivered, but a full cabled report of the proceedings. This is in keeping with the established policy of the MEDICAL RECORD, always to give the latest important scientific news fully, promptly and accurately, from any part of the globe. It is only by such means that we can keep abreast of the times and can make the MEDICAL RECORD a necessity for the studious and progressive practitioner. Thus, in this instance, the man at home gets the published report before it is possible for a member of the Congress to obtain it in Madrid.

THE INHERITANCE OF SYPHILIS.

ON the basis of a comprehensive study of the literature, and of his own observations, Dr. Rudolf Matzenauer discusses, in the *Wiener klinische Wochenschrift* for February 12, 1903, the possibility of inheritance from the father. Inheritance from the mother can conceivably occur via infected ovule or through infection via the placenta, the former, of course, only in women syphilitic before conception. Though Kassowitz denied infection via the placenta, there are now on record more than sixty cases, accurately described, of such infection, and every syphiliologist sees such cases. Like all inheritance of syphilis, inheritance from the mother infected during pregnancy does not always occur. In general it is the more probable, and the intensity of the disease is, as a rule, the greater the earlier in pregnancy the mother is infected. A definite prognosis as to the child is impossible. It is generally accepted that infection during the last two months of pregnancy can be communicated to the child, however there is no certain case of such infection on record. There is no evidence for inheritance via the ovule in any other disease, nor is there any such evidence in particular for syphilis. It is to be accepted that the placenta represents the avenue of entrance. And accordantly with this we may have one twin healthy, the other syphilitic. The intensity of infantile syphilis does not

always correspond to that of the disease in the mother. Thus, severely affected children may come from mothers with latent syphilis. The difference in intensity is to be explained by the inequality of resistive power in the mother and child, who are to be regarded as two separate organisms. In women affected early in pregnancy abortions and premature births are frequent. On the other hand, in proportion to the length of time that has elapsed since infection, the tendency to give birth to severely affected infants diminishes. This gradual attenuation of hereditary syphilis is probably due to a relatively greater frequency of placental disease in cases of recent, and consequently more virulent, maternal syphilis. One phenomenon which has been disregarded or undervalued by most authors is the occurrence of an alternating inheritance, which also occurs with other infectious diseases (*e. g.* tuberculosis); that is, the birth of a healthy child following that of a diseased one. The author then gives a table showing the *pros* and *cons* upon the question of the possibility of direct inheritance from the father, for the existence of which he is convinced there is no evidence, all inheritance being, in his opinion, secondary to infection of the mother. "The sperm of a syphilitic is not infectious." His reasons are that we know no other infectious disease transmitted via the spermatozoa; that there are many more syphilitic fathers than syphilitic children (Fournier); that with increasing exactness of observation, cases of conjecturally certain cases of paternal transmission are progressively more rare and are regarded by the most experienced syphilographers as exceptional; that the transmission of syphilis after many years from man to woman by contact infection, is at least as probable as a direct paternal transmission to the fœtus after so long a time; that apparently healthy women have had syphilitic children not only by their first and syphilitic husband, but also by a second and even a third healthy man; and that in the case of twins, one healthy, the other syphilitic, the explanation presupposes separate placentæ, one of which was diseased. Demanding the evidence which would warrant the usual affirmative answer to the question: Can a non-syphilitic give birth to a syphilitic child? the author points out the comparative infrequency of genital examinations in women, and the ease with which syphilis in them can be overlooked. The number of apparently healthy mothers of syphilitic children reaches *ad maximum* 20 to 38 per cent., but this need occasion no surprise, inasmuch as in 30 to 40 per cent. of cases with certain, tertiary phenomena, previous syphilis is not demonstrable. Syphilis and hereditary syphilis, are one and the same diseases. Now it is a matter of experience that all mothers (consequently also the apparently healthy ones) of children with hereditary syphilis are immune against the syphilis (Colles-Beaumès' law), not only of their own child but against contact infection from other sources. In this fact most syphilographers see evidence that the mother in question is not actually healthy, but only latently syphilitic. On the contrary, the supporters of the possibility of paternal transmission, support themselves upon exceptions to the Colles-Beaumès law. The author, however, finds on record only thirty cases of such alleged exceptions, not one of which can be accepted as fulfilling the requirements of to-day. Every mother of an hereditary-syphilitic child is then without exception, immune. The significance of this has, however, been underestimated by reason of the opinion that existing immunity is no evidence for the previous existence of infection. But with other infectious diseases we have no evidence of a *lasting* immunity apart from a previous attack of the disease in question; that is to say, immunity brought about by antitoxins is always transitory; and, furthermore, in the case of syphilis no immunity is inherited, as is shown by six cases of primary infection of the child by the mother during parturition. Profeta's law, therefore, must be allowed to fall, as invalidated by facts. For one series of sixteen cases, undoubtedly correctly observed, exists in which healthy children of recently syphilitic mothers were infected with syphilis soon after birth. Also, in the case of endemic syphilis, children in the first years of life have acquired syphilis, and among them there must have been some of syphilitic mothers. As then, on the one side, there is no such thing as inheritance of a lasting immunity; and, on the other side, every apparently healthy mother of an hereditary-syphilitic child is without exception permanently immune, it follows that every apparently healthy, but immune mother has (latent) syphilis. And the practical consequences are: the mother of a syphilitic child, even though she show no symptoms, must be treated with mercury; the mother of a syphilitic child can, in accordance with Colles-Beaumès' law, nurse her child without fear; the syphilitic parents of a healthy child may possibly infect the child; and a syphilitic man, in order to avoid infection of the woman, is not to contract marriage until several years after infection, and not without several mercurial treatments. The whole doctrine of the inheritance of syphilis is now much simplified. Formerly composed of traditional hypotheses, woven around with a mass of dicta, syphilitic inheritance has hitherto been regarded as a kind different from that of other infectious diseases, as one in which "no rule without exception" could obtain; whereas now we see it governed by exactly the same laws of nature as in the case of the other infectious diseases.

THE SANITARY MENACE OF CHINA.

In view of the recent commercial opening up of China, the establishment of new lines of communication with that country, and with an already vast and rapidly increasing trade with Eastern Asia, the sanitary condition of China has ceased to be a negligible quantity and has become a matter of the most serious importance to the United States and European nations. Chinese cities are greatly overcrowded both in respect to closeness of buildings and number of their inmates, have no sewerage systems or general water supplies, and are dirty and unsanitary in the extreme. Smallpox is always rife among them, cholera claims its countless victims at frequent intervals, and the large towns have literally become plague centers. It was from China that plague lately entered California, Mexico, the Hawaiian Islands and the Philippines, and the infection from which the present destructive cholera epidemic in the Philippines was developed was introduced into Manila from Canton. Japan has lately been

cursed with plague and cholera due to infections brought in from China, in spite of the excellence of the Japanese quarantine service. Considering these facts, and others which might readily be adduced, it is evident that China, with her total lack of sanitation, is a constant menace to the public health of the more civilized nations. At present, and for some time to come, the so-called "Yellow Peril" is more to be feared for its influence on the world's health than in its relation to commercial competition and military supremacy. It cannot be too strongly emphasized that the time has passed forever when the sanitary condition of Eastern Asia is of no importance to the United States. With improved means of communication and a trade increasing by leaps and bounds, China is neither as isolated nor as far away from us as she was even a decade ago, and she can be no longer ignored as an ever-threatening source of danger. It should not be forgotten that the China coast is not two days' run by steamer from our new Philippine dependencies, and scarcely three weeks distant from San Francisco. This modern improvement in communication has necessarily been accompanied by corresponding increase in the danger of transporting infectious disease—the more ships and goods, the more possible carriers of infection, and the shorter the time consumed in the voyage, the greater the chance that relatively non-resistant micro-organisms, like the cholera germ, will be brought to a home port in viable condition. While something in the way of protection can be done by stationing medical officers at the main shipping centers to watch outgoing ships, as is now done by the Maine Hospital Service, experience has repeatedly shown that this measure is insufficient, and that sooner or later disease will creep by the watchers. The root of the evil exists in the foully unsanitary conditions of the Chinese cities themselves; and these conditions should be remedied, either by exerting pressure on the Chinese authorities to make the necessary changes, or by turning over the sanitary control of the more important seaports to some of the great political powers. The conditions present are fast becoming an international sanitary problem of the utmost gravity, and precedent is not wanting for interference with China with respect to sanitary administration. The European nations have found it necessary to unite in demanding of Turkey that certain sanitary reforms be carried out in connection with the Mohammedan pilgrimages to Mecca, and the constant menace from unsanitary Cuba was no small factor in bringing about the war with Spain. An excellent opportunity for coercing China into carrying out some urgently needed sanitary reforms was lost after the allies evacuated Pekin a couple of years ago, but it would seem as if present unrest and rebellion in that country might result in outside interference becoming necessary at an early date, and with such interference the carrying out of certain radical sanitary improvements in the Chinese seaports should be one of the essentials in coming to a final understanding. From its geographical position, and that of the Philippine Islands, the United States is more directly concerned in the carrying out of the necessary sanitary reforms than is any other nation except Japan. The danger to us from the epidemic diseases of China is both constant and great, and this danger must inevitably increase with the progress of time. There is no question but that unsanitary China is a threat against the public health in the United States and throughout the civilized world, and that the sanitary problem which must be solved is one which presents peculiar difficulties of solution.

Is Nerve Energy Electricity?

In the *Journal of the American Medical Association* for March 7, 1903, Dr. J. Emmet O'Brien maintains by some cogent arguments the identity of these two forms of energy. Strangely enough there has been for a half century a curious unreadiness on the part of physiologists to accept in this matter the simplest hypothesis, though, at the same time, they were not able to adduce any valid counter-arguments. As the author well remarks, the question deserves to be taken up anew in the light of our modern conceptions of the structure of the nervous system, and of our greatly increased knowledge of electricity. Respecting the objection supposed to be derived from the difference in rate of transmission of nerve energy and electricity, the author says that no very decisive experiments as to the speed of nerve impulses have been made since those of Du Bois Reymond and of Helmholtz, and since then we have learned much on the electrical side, especially as to the properties of cables. Further, no laboratory experiments so far made upon the question of the rate at which nerve energy travels are above criticism, and they cannot be held to give an accurate measure of it. Such experiments are, indeed, relatively coarse and inaccurate. O'Brien gives some calculations, based upon the maximum of rapidity of muscular contraction attained by telegraphers, to show that a greater (and not impossibly a much greater) degree of rapidity is attained, than that usually assigned—namely, thirty meters per second. Further, the speed of electricity is, he thinks, much slower than its well-known maximum velocity, for there is a lag in cables due to capacity, inductive static charge, and the electric reaction of armor. Moreover, we now know that insulation is merely relative, and what we know of high-frequency currents has enlarged this view. For instance, a less perfect insulation will suffice for fine telephone currents. A rather detailed consideration is then given of the probable electric properties and functions of the neurones, and of certain terminal organs such as the tactile papillæ, Meissner's corpuscles, etc. The author then says that "If the proposition can be accepted that nerve force is electrical, it will, I think, advance knowledge." And he concludes that: The construction of nerves has been closely, though unconsciously, imitated in electric cables. Experiments on nerves should be interpreted according to the electrical peculiarities of cables, and not as if they were bare conductors. Nerves are insulated, distributed and arranged like fine electric conductors. Their purpose and use are the same as the purpose and use of electric conductors—namely, communication from point to point. They convey some form of energy, and there is not such a gulf between its velocity and that of electricity as has been supposed. This force must be electricity because: (1) electricity is always present when nerves act; and (2) electricity is the form of force which would do the work required, and it is the form of force which would work with such construction; (3) because the terminal and central mechanisms connected with the nerves correspond to the terminal and central mechanisms connected with electrical systems of communication and do similar work in sending, receiving, relaying, switching, transforming, accumulating, retarding, distributing

nd translating impressions, and (4) because electricity, with such construction of conductors and f terminal mechanisms, is the only form of force that ve know of that would do all the work required.

Report of the Government Laboratories of the Philippine Islands for 1902.

The opportunities for research into the origin of ropical diseases provided by the American occupaion of the Philippine Islands are practically unmited, and it is in a high degree encouraging to ather from the above report that it is the intention f the United States Government to take advantage f these means of enlarging the present narrow nowledge of the maladies of tropical countries. With this object in view, a new and extensive laboratory building has been planned in Manila, including chemical and biological laboratory. The chemical aboratory will provide space for the analysis of minrals, mineral products and rocks, of water, soils, food roducts, paints, oils, beverages, and other materials. In addition it will be necessary to investigate the natural resources of the islands, and liscover means of improving the products and, if possible, to develop new resources and industries. With this end in view, rooms must also be provided or distillation, for the examination of plant products, and for work in pharmacology, so that the ctual value of supposed medicinal plants can be lecided on the spot where materials are at hand and resh.

The routine work of the biological laboratory involves diagnostic analysis, bacteriological and otherwise, for the various hospitals, municipal physicians, board of health, police force, and other government nstitutions as may have occasion for such services. As this work is quite extensive, considerable space nust be allowed for bacteriological diagnosis. The nvestigation of tropical diseases and the pathological changes brought about by them, both in human beings and in domestic animals, will require he construction of several rooms for the study of heir causation and to accommodate pathology and physiology. The plans of the laboratory have been drawn so as to accommodate all of the work within one building, one half of which will be occupied by he chemical and the other half by the biological aboratory, with storerooms and photographer's rooms held in common.

In planning the new laboratory, says the report, an important circumstance, adding to the value of he laboratories for the Philippine Government, has been kept in mind. It is believed that the fertility of the field for the investigation of tropical diseases and of chemical problems which can only be carried out here, will offer a great attraction to scientific men of high standing. Of late years the desire for the development of science in the tropics has grown among the thoroughly trained men in the laboratories, both of Europe and America, but the facilities for investigation have heretofore been furnished chiefly by equipping and organizing expeditions, the outfit of which must necessarily be limited, owing to the large cost of supplying temporary laboratories, and to their migratory nature. These drawbacks to thorough work would be eliminated, provided the Philippine Government laboratories could supply facilities and room for such scientific expeditions, and it is thoroughly believed that as soon as the announcement of the complete equipment of the institution is made, it will be possible, for limited periods, to draw on the best research talent in the world, without any greater expense to the government than the cost of transportation, and possibly of the living expenses of the men while here.

There can be no doubt that if the necessary funds are forthcoming to build and equip a laboratory at Manila in the best possible manner, that a great work will be done there, a work which will redound to the credit and honor of America, and which will also be of inestimable service to the whole human race. It therefore behooves the government not to be niggardly with money, but appropriate sufficient to make of the Philippine laboratories an enduring monument to American science.

Dengue Fever.

In the report of the government laboratories of the Philippine Islands for 1902 is an account of investigations made in Manila with regard to the etiology of dengue fever. As is well known, this malady is extremely common in certain tropical and sub-tropical regions, and is perhaps more injurious to health than is generally believed. During the past few months the disease has been very prevalent in Manila, and the experimental work performed there respecting its causation is therefore of much interest.

The report refers to the fact that as early as 1885 J. W. McLaughlin, in a study of an epidemic of the disease occurring in Texas—a description of which is given in Hare's System of Practical Therapeutics, Vol. II, 1901—held that he had discovered and isolated the specific organism from the blood of the patients affected. It was claimed that this organism, a micrococcus, was found both in fresh coverslip preparations and in cultures taken from the blood. The unique features of this coccus, according to the author, was the peculiar manner in which the bacteria grouped themselves when grown on artificial media. The blood of the patient was used first as a culture media for the organism contained therein. In 1897, in another epidemic of dengue fever in Texas, Gamon took up this work and succeeded in isolating a coccus from the blood of one case, which, however, presented some differences from the organism described by McLaughlin, and which the author considered, perhaps, a variety of one of the pus organisms. It was, however, not pathogenic for rabbits in large doses.

H. Graham of Beirut, Syria, described an epidemic of dengue fever, which occurred there in 1902, in the Medical Record, February 8, of that year. He claimed that he had found an ameboid form in certain of the red blood-corpuscles of those sick with the disease, and subsequently he was able to discover it after careful examination in all of the cases, without exception, which he examined. One hundred cases were studied. He describes this parasite as resembling in many ways the plasmodium of malaria, or particularly Pirosoma bigeminum, but its cycle of reproduction is so much longer than that of the malarial parasite that it is difficult to follow. It may be seen either in the center of a red blood-corpuscle or sometimes at the margin. From time to time it changes its shape, showing ameboid movement and shifting its place from one part of the corpuscle to another. This hematozoon is unpigmented. Flagellated forms are described, which, however, only developed after the blood had stood for some time. The author states that the parasite need not be mistaken for a vacuole, as it is too dull in color and lacks the clear brightness seen in a vacuole.

The report goes on to say that during the present epidemic in Manila this plasmodium has been care-

fully sought for in the blood, and attempts have been made to isolate the coccus described by McLaughlin. From these studies the following conclusions were arrived at: (1) In dengue fever there is no leucocytosis. (2) The differential counts of the white corpuscles in this disease show normal proportions of the several varieties. (3) The hematozoon described by Graham has not been found present in the circulating blood of the cases examined. (4) The micrococcus described by McLaughlin has not been encountered. (5) The etiological factor of the disease is as yet unknown. Experiments are now being undertaken to determine whether the disease is disseminated by mosquitos, as Graham has claimed.

Subway Locomotion.

The approaching completion of the New York subway suggests certain important sanitary considerations. The subway question has recently been discussed in the *Practitioner*, and some interesting facts are presented. The chief cause of the movement of air in the tunnels, stations, elevators, and the stairways is the passage of trains which act, in a general way, like the piston of a cylinder driving the air before them, and sucking it in after them. In addition, in the Boston subway (and we presume the same plan will be followed in New York), there are electric fans located in what would be "dead" spaces between stations and air inlets. These fans keep the air in motion, and thus maintain an atmospheric condition practically the same as that outside.

In some of the London "tubes," which the trains used therein pretty closely fill the conditions, are not as favorable as those enumerated in the foregoing paragraph. In the newer structures the amount of CO_2 present was never more than three times that in the outer air (4 parts per 10,000). In the tunnel first built, the air showed CO_2 in the proportion of 25.9 parts per 10,000. Quite recently Mr. Sutherland, F.C.S., made some analysis of the air in one of the London tubes, finding that during the periods of light traffic, when the number of passengers conveyed in the cars was small, the air of the railway was fairly pure; during heavy traffic, however, the proportion of CO_2 rapidly augmented On various occasions in the busy times he found the air of the carriages to contain from 15 to 20.5 parts of CO_2 per 10,000—or from four to five times as much as in the outer atmosphere. It must be remembered that this excess of CO_3 is solely derived from human respiration and skin-transpiration, for there is no combustion of fuel or gas, as in the old underground railways, to augment the impurity of the air.

The *Practitioner* goes on to urge the strict enforcement of the following sanitary regulations: (1) The used air of all underground transportation conduits should be removed daily and renewed with fresh air between the hours of running. The large size of the New York subway and the continuous passage of trains, night as well as day, would probably prevent the danger implied in this regulation. (2) Every person spitting in tunnel or car should be prosecuted, and (3) overcrowding beyond the seating capacity of the cars should be absolutely prohibited.

Another point worthy of mention is that those traveling in subways lose much of the benefit that now comes from surface travel by reason of sunlight. Subways are, of necessity, constantly lighted by some artificial means and though electricity is far superior to gas, it can never replace sunlight.

Dr. Maclagan's Gift to Humanity.

Death has recently removed from the ranks of medical practitioners one whose name will ever be associated with the introduction into therapeutics of a remedy which has many a time and oft lessened the pains of suffering humanity. We refer to the late Thomas John Maclagan of Edinburgh, whose great work was the discovery of the curative action of salicin, and from that of the salicylates in acute rheumatism. The introduction of this remedy practically effected a revolution in the treatment of this disease. It shortened its duration, lessened the severity of its symptoms and greatly prevented its sequelæ. But twenty-seven years have elapsed since his original contribution was published in the *Lancet*. His investigations were made purely on empirical grounds. His name will always be associated with the theory of the miasmatic origin of the disease. He reasoned that nature commonly furnishes a cure in places afflicted with diseases of that type, and he was thus led to experiment with the bark of salix alba, and with meadow sweet. He obtained his medical degree in 1860, came to London in 1879, and soon took a high rank among the leaders of the city. He died at the age of sixty-five years.

News of the Week.

The Discovery of the Smallpox Germ.—Prof. W. T. Councilman of the Harvard Medical School has announced his discovery of the causative element of variola in the shape of a protozoon, the first development of which appeared to be in the pustular eruption. So far this is the first demonstration of the existence of an annual parasite in an eruptive disease, and may give promise of many interesting observations along similar lines.

American Medical Association.—Tickets issued by the Southern Railway to New Orleans for the American Medical Association will be good for a stopover at Washington on the return trip, on deposit, for ten days not to exceed May 30, in order to enable the holders of such tickets to attend the Congress of American Physicians and Surgeons at Washington.

Changes in the Faculty of the College of Physicians and Surgeons, New York.—Dr. Geo. L. Peabody has resigned as Professor of Materia Medica and Therapeutics, to be succeeded by Dr. Christian A. Herter. Dr. Geo. M. Tuttle has resigned as Professor of Gynecology and Dr. E. B. Cragin has been placed in that department. Dr. John D. Voorhees has been appointed lecturer in obstetrics, Dr. Arnold Knapp has been appointed lecturer on ophthalmology to succeed his father. Dr. Geo. C. Freeborn has resigned as instructor in normal histology, and Dr. Robert F. Weir, who has been connected with the institution as teacher for more than thirty years has also resigned, to be succeeded by Dr. Joseph A. Blake.

Award to Woman Scientist.—The prize of $1,000, offered two years ago for the best piece of scientific research work done by a woman, was awarded to Dr. Florence R. Sabin, assistant in anatomy at the Johns Hopkins University Medical School. Dr. Sabin presented the results of an investigation on the origin of the lymphatic system.

Bill for Limiting Hours of Labor Passed in New York State.—Governor Odell has signed Senator Hill's bill regulating the hours of labor of women and children in mercantile and other establishments. The Hill bill applies to all minors under sixteen employed in "any mercantile establishment, business

office, or telegraph office, restaurant, hotel, apartment house, or in the distribution or transmission of merchandise or messages." It forbids their employment for more than fifty-four hours per week, or for more than nine hours in any one day, or before 7 A.M. or after 10 P.M. Women between sixteen and twenty-one years old, employed in mercantile establishments, such as department stores, are limited to sixty hours' work a week, or ten hours in any day, except for the purpose of making a shorter workday on some other day. Their hours, also, are limited from 7 A.M. to 10 P.M. The law requires as a condition for labor of children school attendance of not less than 130 days during the school year previous to a child's fourteenth birthday. Work during vacations is permitted by children over twelve years old. The law takes effect October 1.

Annual Report of Roosevelt Hospital.—The annual report of Roosevelt Hospital has just been made public, and shows that the number of patients under treatment in the year 1902—3,874—was greater by 104 than in the preceding year, and the daily average of patients larger by 12 than in 1901. The number of cases treated in the emergency department was 8,339, or 281 in advance of any highest previous record. The record in the "out-patient" department shows an increase of treatments, which is considered an encouraging sign in view of the falling off in many of the dispensaries. The money donations to the hospital were few in number, the total amounting to only $5,113.31, while the expenses for the year were $172,593.62—$13,928.32 greater than in the previous year. The report calls attention to the urgent need of increasing the endowment fund by $500,000. No bed was endowed during 1902, and the keeping down of the annual deficit to $6,208.23 was due to the increase in patronage of the private patients' pavilion.

Faculty of Veterinary Medicine Dissolved at McGill University.—The Board of Governors of McGill University have decided that the faculty of comparative medicine and veterinary science at the university shall cease to exist at the close of the present session. The reason given for this step is the impossibility of securing adequate funds for the reorganization of the faculty along the lines suggested by the governing staff of the university.

Preparing to Welcome Professor Timiziazeff in London.—Scientific men, says the New York *Tribune* of April 26, are preparing to welcome Professor Timiziazeff, the Russian scientist when he lectures before the Royal Society next week, and there will be a general rally of the learned professions when Pierre Curie and Madam Curie, the experimenters in radium, are entertained at the royal institution in June.

Land for Rockefeller Institute.—Final contracts were signed on April 27 for the purchase of land from the Schermerhorn estate for the proposed Rockefeller Institute. The property acquired extends from Sixty-fourth street to a line fifty feet north of Sixty-seventh Street, and from Avenue A to the East River. The price was about $700,000.

Alcohol in Patent Medicines.—One of the most sensible things done by a Women's Christian Temperance Union worker is to ask the Massachusetts Board of Health to analyze several well-known patent medicines in order to determine the amount of alcohol contained. There is only too much reason to believe that the revelation thus made will not discourage the use of these articles as much as it might. The truth may already be known to many who have adopted the particular form of tippling here indicated. To some, however, the exposure may serve as a restraint. It is calculated to promote honesty, too, in makers of proprietary "medicines" and their users.

Dr. Wyman on Yellow Fever in Cuba.—The Marine Hospital Service and the boards of health of several of the Southern States do not agree as to the necessity for special precautions against the introduction of yellow fever from Cuba. The Louisiana Board of Health insist on the disinfection of vessels arriving at ports in that State from Havana and other Cuban ports, and the authorities in Alabama have taken a similar course. Surgeon-General Wyman, however, emphatically states, that the time has passed when it was necessary to disinfect every ship that arrived at a Southern port from Cuba. Dr. Wyman further declares that Havana can no longer be regarded as an "endemic center" of disease, for, under American rule followed by the new insular government, Havana has become one of the most healthy cities of the world.

League of Women for the Protection of Birds in Europe.—The League of Women for the Protection of Birds in Europe is spreading with remarkable celerity. It was founded in 1899. It now has branches in Great Britain, France, Switzerland, Germany, Austria, Russia, and Holland. The Geneva branch of the league has just issued an appeal to women asking them not to encourage the slaughter of birds for millinery purposes.

Obituary Notes.—Dr. FRANKLIN A. SHERMAN died on April 22, in Ballston, N. Y., aged seventy-four years. He was born in Castleton, Vt., and was a cousin of the late Admiral Philip and Commander Edward T. Woodward of the United States Navy.

Mrs. ANNIE E. SHIPMAN, widow of Dr. George E. Shipman, after more than twenty years spent in charitable work, died on April 24, at the Foundlings' Home, Chicago, of which she had been Superintendent since the death of Dr. Shipman, ten years ago. The deceased lady was seventy-nine years of age, but remained in active management of the institution until seized with pneumonia two months ago. Dr. and Mrs. Shipman came to Chicago in 1846, and immediately took up work amongst foundlings, and out of this work, began upon quite a small scale, grew the institution which has developed from a few rooms in a frame structure rented in January, 1871, to a commodious institution, where an average of fifty children and forty mothers are cared for each year.

Fourth Pan-American Medical Congress.—At a meeting of the International Executive Committee of the Pan-American Medical Congress, held April 1, 1903, it was decided to accept the proposal of the Argentine Republic to hold the Fourth Pan-American Medical Congress in Buenos Ayres in 1905, instead of 1903, as had been announced in their invitation of February, 1901.

This was considered by the Committee much more advantageous for the meeting, as it has long since been realized that it would have been impossible to have had a good representation of the delegates from this and other countries, had the convention been held there in June of this year.

The meeting of the American Medical Association in New Orleans and of the Congress of Physicians and Surgeons in Washington would have prevented a number of physicians of this country from attending; while the meeting of the International Medical Congress in Madrid would probably have attracted many from Spanish-American countries who would

otherwise have been disposed to have taken an active interest in it.

Pathological Society of Philadelphia.—At a stated meeting held April 23, Dr. Aldred Scott Warthin of the University of Michigan presented by invitation a communication entitled "The Hæmolymph Nodes, with Especial Reference to Their Relations to Adipose Tissue." He described the several varieties of nodes and maintained that they are structures sui generis and not mere forms of lymphatic glands. He considers them hæmolytic in function, and he was able to trace their origin from fatty tissue. They communicate with the systemic circulation. At the close of the meeting a reception was tendered Dr. Warthin.

Tennessee State Medical Association.—At the seventieth annual meeting of this time-honored and progressive organization held in Nashville on April 14, 15 and 16, the following officers were elected: *President*, Dr. J. A. McSwain, of Paris; *Vice-Presidents*, Drs. W. H. W. Sale of Covington; Louis LeRoy of Nashville, and Dr. C. P. Fox of Greeneville. Dr. Deering J. Roberts of Nashville was re-elected Secretary; and Dr. W. C. Bilbro of Murfreesboro, Treasurer. The prize of $50 for the best essay, one-half being furnished by the Committee of Arrangements of this city two years ago, the other half by Dr. Deering J. Roberts last year, was awarded to Dr. E. C. Ellett, of Memphis. The Association will meet on the second Tuesday in April, 1904, in Chattanooga.

Philadelphia County Medical Society.—At a stated meeting, held April 22, Dr. Edwin E. Graham read a paper entitled "Modification of Milk for Infant Feeding;" Dr. David L. Edsall a paper entitled "Biological Differences of Milk;" and Dr. Samuel McC. Hamill a paper entitled "Milk as a Carrier of Infection."

The American Gastro-enterological Association will hold its sixth annual meeting at "The Shoreham." Washington, D. C., May 14.

The West Virginia State Medical Association will hold its thirty-sixth annual meeting at Charleston, W. Va., May 26, 27 and 28, 1903.

Obituary Notes.—Dr. James M. Brown died in Philadelphia on April 12, at the age of fifty-one years He was graduated from Jefferson Medical College in 1883.

Dr. S. G. Godshall died at Edge Hill, Montgomery Co., Pa., on April 4, at the age of forty-three years.

Dr. J. M. Allen died at Chester, Pa , on April 20, in this eighty-fifth year. He was a graduate of the medical department of the University of Pennsylvania and he served as a surgeon during the Civil War in the Forty-fifth Regiment, Pennsylvania Infantry.

Two Cases of Diplococcal Septicæmia.—M. Frederici reports two fatal cases in which the diplococcus was found to be the cause of the infection. The first was postpartum; the second occurred in a girl whose menses were suppressed from the effects of a cold bath taken during intense sweating. In both there was marked disproportion between the importance of the objective symptoms and the absence of subjective symptoms; from the beginning to the end of the infective process there was apparently no suffering whatsoever. The temperature also was unusual in that for the most part it kept within normal limits, rising occasionally a little in the evening. The kidneys and the liver were the seat of inflammatory processes due to the microorganism, but the lungs and the endocardium, which are usually points of predilection for the diplococcus, remained intact.—*Revista Critica di Clinica Medica.*

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent.)

IMMUNITY—LIVERPOOL TROPICAL SCHOOL—LONDON HOSPITAL SCHOOL—BRIBES TO BE VACCINATED—SMALLPOX OUTBREAKS—HOSPITAL SATURDAY—P.R.C.P.—BIRMINGHAM M.O.H.—OBITUARY NOTES.

London, April 10, 1903.

The Goulstonian Lectures for this year have been delivered and reported at length in the journals. The lecturer was Dr. Grünbaum of Liverpool, who, in a graceful recognition of the honor conferred, attended especially to the desire of the founder that the lecturer should be chosen from among the four youngest doctors of the College of Physicians. This wish is interpreted by the College to be one of the four most recently elected to the Fellowship, as you know this honor—if honor it be—is attained by members of the college by a process of electioneering, which means "getting at" the influential officials for the time being. Howbeit, Dr. Grünbaum is not only a recently promoted member, but is one of our younger physicians, his first qualification being dated 1894 and his M.D., Cambridge 1897. But he has achieved such distinction by his scientific work that when a director of the cancer research in Liverpool was required, the choice naturally fell on him. The invitation to deliver the three Goulstonian lectures almost as naturally followed, and he took for his subject, "Theories of Immunity and Their Clinical Application." If a little abstruse, the statement of the subject, in its present position, seems well adapted for a select audience, though perhaps more easily grasped in print. A correspondent of the *Lancet*, however, takes exception to his journal being occupied with it and wants to know "What is the use of all these cytophiles and haptophores?" and adds that "the explanatory figures might suggest new ideas to the designers of carpets or wall papers, but do not convey a particle of useful information" to his mind. I am afraid I can offer him no comfort, unless he is prepared to make a serious effort to grasp the subject. If he cannot compel his mind to fix close attention to the lectures, he may as well turn over the leaves of his paper and find other matter more to his taste.

It would be idle to attempt here the exposition of Ehrlich's and Metchnikoff's theories—the only two given in detail by Dr. Grünbaum. These two, originally opposed to one another, like the humoral and iatrochemical theories of the middle ages, the lecturer regards as only rays of light refracted at different angles from the same source which will ultimately fuse into one brilliant cellulo-humoral theory of immunity. The rivalry of the exponents of the two theories has only led to the most interesting experiments of biological investigation.

Passing to some of the applications of the theory the lecturer pointed out that the antitoxins are antidotes of the cell products which are the toxins, but there is not complete agreement as to their mode of formation. Some animals are very susceptible to tetanus toxin however introduced; others are only affected when the poison is introduced intra-cerebrally, but in these it is found that the toxin is fixed in other tissues. Hæmolysius may be regarded as antidotes resulting from the introduction of alien blood into an organism. But many substances will cause hæmolysis, which has perhaps received more investigation than other parts of the theory of immunity, but is less generally known.

In the treatment of myxœdema one can hardly suppose the few grains of thyroid gland given per diem replace the normal activity—and yet a large dose produces toxic effects. Perhaps the therapeutic effect is due to the production of an antitoxin to the toxin of the thyroid. Normally the antitoxin should be elaborated by the gland itself, but it may be prepared vicariously by other cells in the absence of thyroid. Conversely, the indifferent results obtained with pancreatic extract in diabetes, and with suprarenal extract in Addison's disease are explicable. The function of these glands is not to neutralize, but to elaborate. The use of the extracts, therefore, will neither replace the activity of the glands nor stimulate other cells to perform vicariously such functions. The tentative administration of organs corresponding to those diseased has led to much disappointment, but it is not so dangerous as to prevent trial As vaccination began with smallpox and was successful from the first, so did antitoxin succeed in diphtheria and thyroid in myxœdema.

Among other practical applications referred to in these lectures I may cite the obvious one that any antitoxic serum should be used as soon as a diagnosis is formed. A curative serum may often be given by the mouth, as many antidotes are not destroyed by digestion. Sera undergo

rapid change, and should therefore be used as fresh as possible.

With regard to protective inoculation and infection, the most complete immunity is generally through an attack of the disease. It is certainly so with smallpox, and probably with other diseases. A mild attack is also more protective than a severe one. Dr. Grünbaum offered explanations of these and other facts in accordance with Ehrlich's theory, and further discussed relapses, reinfections, predispositions, serum, diagnosis, etc.

The infectivity of infectious fevers he thought could not be all of one kind. Yellow fever until lately was held to be very infectious, but is really spread by mosquitos, though the pathogenic microbe has not been found. Can the infectious diseases of temperate climates be spread in a similar way? To this question the lecturer would reply, "It seems possible, but unlikely."

The Liverpool School of Tropical Medicine has just issued its anual report, which shows steady progress. Four expeditions were dispatched during the year. For a second time Major Ronald Ross was sent to Sierra Leone, and in September he went to Ismailia on the invitation of the President of the Suez Canal to investigate malaria in that region. The school received the thanks of the Suez Company. Drs. Dutton and Todd were sent to Gambia and French Senegal to investigate trypanosomiasis, and it is proposed to send these gentlemen to the Congo Free State. Dr. Logan Taylor went to the Gold Coast Colony to investigate the unsatisfactory health condition of Europeans there, and carry out sanitary reforms. The employees of Liverpool firms proceeding to the tropics can now attend lectures to instruct them on the precautions to observe, and simple instructions for the preservation of health in the tropics are ready for distribution. Altogether a good year's record.

The Medical School of the London Hospital issued at the beginning of the week an appeal for funds to endow the college as one of the most important medical educational establishments, and as one contributing the services of well-trained men to the hospital wards.

Of course, this is very shocking to the antivivisection cranks, and the Hon. Stephen Coleridge is again to the fore with a letter to the papers denouncing the hospital and school, and demanding the accounts of the latter. But he is told by one editor this morning, that as he is not likely to subscribe, he has no right to such accounts, and that from what he has been told before, he need not be surprised that they are not sent to him.

I suppose, as standing counsel to the anti-society, he feels he must make foolish demands to earn his fees.

Dr. Louis Parkes records in his report as M. O. H. for Chelsea, a curious, perhaps unique, instance of a plan of promoting revaccination. It is something like a scheme of bribery. When some cases occurred in a lodging-house a lady placed a sum of money at the disposal of Dr. Parkes to induce the inmates to protect themselves. More than 200 inmates of Chelsea lodging-houses submitted to revaccination, and the spread of the disease was arrested at a time when further cases were expected. The cost worked out at about half-a-crown per case, including "the initial monetary inducement," and compensation for disablement in a "certain small proportion of cases." A class of people very likely to carry about contagion, and very reluctant to submit to vaccination, were thus induced to protect themselves and the community.

Outbreaks of smallpox continue to occur from time to time in various localities. At Croydon it was stated on Monday that fourteen cases had been removed to the smallpox hospital at Cheam. The outbreak began in the workhouse infirmary. On Tuesday the death of one of the patients was reported, and a new case had been notified and removed to the hospital. Great efforts at isolation are made, but it is feared that two contacts with the first case who left the infirmary cannot be traced.

At Kingston-on-Thames four cases were notified in the common lodging-house where forty persons slept. The disease is supposed to have been brought by a tramp who had slept in an infected place, and developed it after entering the workhouse. The cases were at once removed to the hospital.

There were fifteen cases in the Dublin isolation hospital, where three have died. There are fifty-five in the convalescent stage. A scandal has arisen respecting the treatment of the cases isolated, some reports alleging that the patients had not clothes and were overcrowded. Sir C. Cameron says the matter was grossly exaggerated, and those whose clothes were removed were ordered to remain in bed. Sir Charles may, perhaps, think it necessary for him to maintain stricter discipline over the nurses and officials to see that his orders are carried out.

Several towns in the north of England and Scotland have had cases. In London, too, some fresh cases have occurred, and on Tuesday there were fifteen in the Asylums Board Hospitals.

The annual meeting of the Hospital Saturday Fund was held on the 4th inst. The income for 1902 was £22,964, the highest figure yet reached and more than £1,400 above that of the preceding year. The total expenses were £2,365 or 10.3 per cent, as against 10.74 in 1901.

Sir Wm. S. Church, Bart., K.C.B., etc., has been re-elected President of the Royal College of Physicians.

Dr. A. Hill has resigned the post of M. O. H. for Birmingham, which he has held since 1872. He is now in his seventy-seventh year, and after his long and able career carries into retirement the good wishes of the community he has served so well, and of everyone interested in the advancement of public health.

Mr. Edwin Chesshire, Consulting Surgeon to the Birmingham and Midland Eye Hospital, died on 1st instant, aged eighty-four years. He took the M.R.C.S. in 1841, and became a Fellow in 1857. He was a member of the Ophthalmic Congress, Brussels, and a contributor to the journals on ophthalmic subjects.

The death is also announced of Richard Alford, aged eighty-seven, R.C.S. (1855), who qualified in 1838. He was Consulting Surgeon to the Weston-super-mare Hospital, indeed one of its founders. He practised in that pleasant town from 1855 to 1886, when he retired.

Another octogenarian, W. B. Kellock, F.R.C.S. (1878), member 1843, died on the 3d instant, aged eighty-two years.

Dr. Solomon C. Smith died on the 5th inst., aged sixty-one years. He qualified in 1863 and settled in Halifax, where his father was a surgeon. In 1892 he came to London and joined the College of Physicians. He became editor of the *Hospital*, a journal established by Sir H. Burdett, and which is devoted to nursing and hospital management.

The death is also announced of Lieutenant-Colonel W. H. Neilson, M.B., C.M., of the Indian Medical Service, which he entered in 1882. His health had been failing for some time, and he died in India on the 23d ult., at the age of forty-nine years.

I must also note the decease of Mr. E. W. Tait, one of the most esteemed practitioners in the north of London, where he settled in 1852, and continued until 1890, when failing health induced him to retire. He carried into his retirement the respect and even affection of all his neighboring confrères. He died on the 31st ult., aged seventy-three years.

OUR LETTER FROM THE PHILIPPINES.

(From Our Special Correspondent.)

MANILA, March 10.

THE work of enumeration for the census of the inhabitants of the Philippines was begun recently. As the matter of preliminary organization has been very thoroughly carried out, it is believed that the results will be very satisfactory. The health work has been very much hampered, particularly during the cholera epidemic, because of the fact that there were no reliable figures for the population of the archipelago upon which sanitary statistics could be based.

Since mention was made in a previous letter of the insufficient free medical attendance provided for the natives in Manila, several Filipino physicians have been attached to each municipal sanitary substation. The fact that their services can now be secured gratis has not yet been realized by the natives, who have always been accustomed to pay for all medical services—as under the Spanish régime the few physicians in Manila did not indulge in the luxury of charity practices, and natives who had no money knew that it was useless to ask for medical attention. As a result of this failure to appreciate that times have changed for the better, many deaths are still occurring in which no effort was made to seek medical attention for the sufferer, though the gratuitous services of physicians could have been had by applying to sanitary stations, which might be only a few yards distant from the home of the sick person. The health authorities are taking steps to acquaint the indigent with the fact that free medical attendance can now be secured. As already mentioned, the fatalistic ideas and religious superstitions of the Filipino operate against his faith in the efficiency of medical treatment, and, like other savages, some of them seem to resemble a stricken animal, which seeks seclusion when it feels disease.

The statistics of the Manila Custom House show that a total of seventy-one physicians came to the Philippines during the year 1902. These medical men were, however, nearly all connected with the government service as surgeons in the Army, Navy and Marine Hospital service, and have had practically no connection with the treatment of the sick among the Filipinos, to the great need for which mention has been made in previous letters. A number of ex-surgeons of the volunteer army have

located in Manila and seem to be doing well in their practice among the American civilian residents, though the number of the latter is not sufficient for the support of more English-speaking physicians than are now here.

The sanitarium at Benguet is so far advanced in construction as to be able to receive a certain number of persons during the coming unhealthful season. The attending physician, Dr. Thomas, announces that the sanitarium cottages will be equipped with all bedroom necessaries, but that they are not provided with cooking facilities or kitchen outfits. A stock company, with abundant capital, has been formed to erect a large hotel and several cottages, and a number of Manila people are already building summer homes there.

A strong company has also been formed to provide suitable accommodations at the Los Banos hot springs, about thirty miles from Manila. The springs resemble the Arkansas hot springs in the character of their water, and are much resorted to by venereal and rheumatic cases. The company has already erected a large carbonating plant and is bottling large quantities of the water for medicinal use elsewhere. The water issues from the springs at a temperature of 212° F.

The military authorities have been sinking a number of driven wells at the new posts for the purpose of securing a water supply of permanent purity. Their efforts have met with desired success except at the post at Bayombang, where the water supply secured at a thousand feet below the surface proved to have strong cathartic properties, and on chemical examination was found to strongly resemble the Hunyadi Janos water.

The appointment has been made of Dr. Thomas R. Marshall, late captain and assistant surgeon U. S. Volunteers, to Chief Health Inspector for the city of Manila. The salary attached to the position is $3,500 per annum. Dr. Marshall has been Acting Chief Health Inspector for some months, and has shown his fitness for the position by his excellent service in connection with the cholera work. He was in charge of one of the large cholera hospitals in Manila during the early period of the epidemic. Other changes in the Board of Health are the appointment of Dr. DeMey as medical superintendent of the leper colony on the island of Kulion, Dr. Wilkinson relieving him in charge of the San Lazaro Hospital in Manila. The latter institution will be maintained as a leper asylum for some months, until suitable accommodations at the new colony have been prepared for the patients at San Lazaro. The patients at the large leper hospital at Cebu will be first removed to the colony on Kulion Island, as the condition of the institution at Cebu is not as good as at the Manila leper asylum. It is expected that nearly all the 3,288 lepers at present known to be in the islands will be transported to Kulion by the end of the present year, after which cases will be promptly sent there as they develop or those now existing in the country districts become known as a result of the gradual improvement in the administration and organization of the sanitary service of the islands.

Another recent appointment is the selection of Dr. Palmer G. Lyon, late assistant surgeon U. S. Volunteers, to be physician at the Bilibid Prison. The pay attached to the position is $2,000 per annum, and quarters for the physician are also provided in the prison.

The Board of Health is making an earnest effort to do away with many of the most unsanitary habitations of the city before the return of the rains, when a recrudescence of cholera is expected. At present particular attention is being given to the Chinese opium dens, which are literally plague spots.

As part of the plan of general sanitary improvement, the municipal authorities of Manila have undertaken to move a number of native families living on Calle San Marcelino and settle them upon city land in the Paco district of the city. This action is taken purely as a sanitary measure, as the houses on Calle San Marcelino are in an insanitary condition. The transfer of the families in question can be the more readily accomplished as the land upon which they are now living belongs to the city. Plans for this transfer have already been prepared. The land in Paco is to be divided into small plots 7 x 9 meters each, which will be rented at the nominal sum of one dollar per month, in quarterly instalments; the assignment of the lots to their future tenants to be made by the city engineer.

More than forty Filipino and Chinese barbers were recently arrested in one day, in the Binondo district, for violation of the municipal ordinance requiring proper sanitary precautions on their part relative to the sterilization of instruments and brushes, good soap, clean hands and the use of clean, white clothing. There is much skin disease among the natives and Chinese, and the many insanitary barber shops were justly regarded as a main factor in its spread. The regulation requiring proper sanitation of the barber shops was passed some time ago, and the recent wholesale arrests were the result of this regulation being persistently ignored by those whom it was intended to control.

There has been a considerable increase in the number of cases of plague in Manila during the past month. The situation is not alarming, but the increase shows the persistency of the infection, under the conditions existing in Manila in spite of the concentration of the efforts of the health authorities against it. The outlook for the early extermination of the disease, short of the use of such far-reaching and drastic measures as the present temper of the Filipinos would render it inadvisable to employ, can scarcely be anticipated. Plague has not yet occurred in the other cities of the Philippines, but as long as it exists in Manila there is an ever present danger of its doing so.

A number of cases of smallpox have occurred in Manila, but these have largely occurred in natives recently arrived from the provinces, where vaccination has not as yet been thoroughly carried out. In Manila nearly all the inhabitants have been vaccinated and the work is being pushed to completion at the rate of about 800 vaccinations a day. In the provinces smallpox prevails to a large extent, but the disease is practically confined to districts in which the work of vaccination has not yet been carried on.

Several cases of cholera have occurred lately in Manila, after an interval of some weeks of freedom from the disease, showing that the infection is still present. From a study of the cases which recently occurred it is believed by the health authorities that they resulted from the use of infected vegetables brought in from the surrounding country; but as the sanitary officials permitted certain wells to be reopened, and their water to be used, shortly before these cases developed, it would seem as if the question of polluted well water must be considered in relation to their development. As the water supply of Manila is insufficient, the discontinuance of the use of well water caused considerable extra labor on the part of the Filipinos in procuring their supply for household use, and they have chafed under the prohibition of the use of their wells. The health authorities believed they were safe in allowing some of these wells to be again used, but it would seem as if they had been mistaken.

Many claims for compensation have lately been presented to the government authorities as a result of the cholera epidemic. The disease spread so rapidly and was so severe that the sanitary officials frequently entered provincial towns in great haste and proceeded to secure inspectors and seize buildings for use as cholera hospitals without first obtaining authority for the necessary expenditure from the local officials. As organization was effected in one town the health authorities would proceed to another, leaving the local health inspectors and practicantes on the hands of the local officials, who now refuse to pay for the services of these men. Many buildings were also burned in the effort to stay the advance of the cholera. The interested parties are now pressing their claims for remuneration for services rendered and property destroyed, and it appears that the general government will be forced to pay for the orders and acts of its subordinates. There is no doubt but that much property was uselessly destroyed during the panic which occurred during the earlier period of the epidemic, and the government has in several instances attempted to hold officials concerned pecuniarily responsible for such destruction. In some other cases property was destroyed by the military with the idea of limiting the infection near army posts. The civil officials now say that no orders were given by them for such destruction, the military have no funds from which the losses can be made good, and hence there is little chance that claims made by the natives to cover such losses due to military action can be satisfied. It is understood that several claims for damages for the destruction of property have been instituted in the courts against the civil and military officials under whom the house burning, etc., was carried out.

Many interesting experiences are now being told by the Americans here in connection with the cholera epidemic, especially as regards the outbreak of the disease among the Mohammedan natives of the southern islands. The sanitary work there was particularly difficult, in view of the belief by the natives that they did not have cholera, but that the Americans were poisoning them. This idea was so generally entertained that Governor Taft, on his recent southern tour, made a public address to reassure the natives on this point. Among the Visayans this alleged poisoning was particularly attributed to their hereditary enemies, the Tagalogs. In one case, a Tagalog was arrested and brought to trial on a charge of poisoning the river from which the water supply was drawn. The evidence consisted of two bottles, one found in the river and the other in the Tagal's house. The Visayans rea-

soned that no one would have placed a bottle in the river unless he had wished to poison the water, that no one would wish to poison the water, but a Tagalog, and that the Tagalog living nearest the river was undoubtedly the guilty party. This belief became conviction when a similar bottle was found in the house of the unfortunate Tagalog. The end of it all was that the victim was brought to court and placed on trial before an American judge, when the chain of evidence was badly shattered by the discovery that the mysterious bottle contained only tooth powder. In spite of this ridiculous turn of affairs, the Tagalogs were not relieved from suspicion, and it is said that several were killed on suspicion in the country districts. Army officers were attacked, sanitary inspectors stoned and murdered, and there was general distrust of all strangers. On the approach of Americans, women would cover their mouths and noses, and if a stranger happened to get between children and the doors of their houses, the children would dart for the thickets, screaming at the top of their voices. The natives were distrustful of all disinfectants except lime, with which they were familiar from its other uses, but in some instances they would not permit the use of any of this substance which had been provided by the sanitary officers, lest it had been converted into a poison as a result of contact with white men. One American school teacher had a guard of thirty or forty men stationed around his house one night, to see if he was a bad man—as was afterward explained. Since he kept his light burning and sat up all night with a cocked Winchester across his knees, it was decided he was not as bad as had been at first supposed. The sanitary inspectors had many exciting experiences; a Filipino's bolo is always kept handy, and under the influence of extreme fear, what little powers of reason and discretion he ordinarily has seem to be soon lost.

There was great difficulty in getting the sanitary machinery to move in the provinces. The people were panic stricken, deaf to reason and argument, and provokingly slow in carrying out orders. The Filipino at his best does not know how to hurry any better than the American knows how to take things easy; and the government sanitary officials were frequently exasperated to the last degree by unnecessary delays; inability to make the natives understand their imminent danger, and the unwillingness of the latter to depart even temporarily from the time-honored, insanitary practices of their forefathers. The chief sanitary inspector of the islands died of heart failure, superinduced by overwork at the time the epidemic first started up, and many of those engaged in the sanitary work broke down under the nervous strain and constant irritation to which they were subjected. With slight modification, the situation here was admirably expressed by Kipling's lines:

"It is not right for the Christian white
To hustle the Aryan brown,
For the Christian rides and the Aryan smiles
And he weareth the Christian down.
And the end of the fight is a tombstone white,
With the name of the late deceased,
And the epitaph drear, 'A fool lies here
Who tried to hustle the East.'"

OUR CONSTANTINOPLE LETTER.

(From Our Special Correspondent.)

TYPHOID FEVER AND OYSTERS—PLAGUE CASES—EXAMINATION FOR MEDICAL LICENSE.

CONSTANTINOPLE, April 7, 1903.

THE winter has been unusually severe; more snow has fallen than for many years past. The cold has been intense, and told somewhat heavily on the aged and increased their mortality. The general health of the population has, however, been good.

Typhoid fever—to which previous allusion has been made—is becoming a comparatively rare affection in the city. This, doubtless, is due to the better water supply, and a still further diminution of the disease may safely be predicted, since H. I. M., the Sultan, has had constructed a hundred public fountains for drinking water from the pure source of "Khiat-Haut" (sweet waters) Many of these faucet-fountains are now in full operation. This is an inestimable boon to the population, from the hygienic point of view.

One of the great questions of the day—oysters as a medium of conveying typhoid fever and other gastro-enteric affections—has been even more fully thrashed out here than in America or England. Not that there have been any outbreaks of disease attributable to oysters or other shell-fish, but that Professor Remlinger of the Bacteriological Department raised the question at the Medical Society, whence the discussion extended to the local press.

Professor Remlinger's views were those of the bacteriologist purely. He demonstrated what was already well known and admitted, *i. e.* that impure oysters produced gastrointestinal troubles, and might become carriers of typhoid fever. He indicated the spots where they might be expected to be found impure, and ended by suggesting certain forms of cooking and condiments as preventive, strongly recommending lemon-juice, which he considered a powerful bactericide.

His views were strongly opposed by Mr. Apery, our Chemical Philosopher, who contended that the picture of danger from oyster-eating was overdrawn, inasmuch as the debatable mollusk was never dredged in the localities indicated by the Professor, but always in well-known places of running water, and that, considering mollusks—including oysters, mussels, clams, etc.—were at certain seasons the chief food of a large part of the population, very few cases of irritant poisoning occurred. Mr. Apery further contended that the question raised was scarcely necessary in Constantinople, and was likely to injure a large industry, which was carried on under conditions entirely different from those of other countries where the oyster was artificially reared in the neighborhood of streams likely to be polluted with town and city sewage. General opinion favors the views of Mr. Apery, and people go on eating oysters and mussels as of yore, little, if at all, scared by this academical discussion.

There has been no recrudescence of plague cases. Quarantine restrictions now apply only to Egypt and the Syrian Coast, and they are made as little burdensome as possible. Von During Pacha, the distinguished dermatologist, has resigned the Turkish service and accepted a professorship in the University of Kiel. His studies of syphilis in Asia Minor are now before the profession. They are instructive and interesting, and will repay perusal. The old "British Seamen's Hospital" has been demolished, and the new one is in course of construction. It will contain accommodations for almost forty patients, and be furnished with up-to-date appliances.

The regulations prescribing that doctors wishing to practise in the Turkish Empire should undergo an examination at the Medical School to obtain the Turkish diploma were wise and necessary. Heretofore the examinations were carried on in Turkish and French, or through the medium of an interpreter when the candidates did not speak these languages. A new regulation ordains that the examinations shall be conducted in Turkish or French only. It is, evidently, assumed that there is no hardship in such a regulation, as every educated physician is supposed to know the French language. This, however, is too large an assumption, which, especially, affects American and English candidates, for the examination, who, though able to read French, have little command of technical medical terms and colloquial aptitude. It thus happens that their examination has to be deferred for an inconvenient period of a few months to "get up" their French. There is no actual injustice in this regulation of the Medical School, based, as I am informed, on the difficulty of always having an impartial translator. But, surely, this might be arranged by the Medical School having its own official interpreter.

APPENDICITIS.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR: It may not be too late to observe that an editorial in the MEDICAL RECORD of November 29, 1902, protests mildly against the conservatism of Broca and the Belgian and French surgeons in general, in the treatment of appendicitis. While you give no statistics of mortality under modern American methods, the 13 per cent. of Broca is not favorably regarded. And yet an eminent New York surgeon, more recently, gave the results of his work showing a larger mortality than Brocas.

Impressions prove nothing, but may be interesting. For instance, the impressions of some of the older men in regard to the comparative frequency and mortality of the perityphlitis of forty years ago and the appendicitis of to-day would be interesting reading. If the discussion involved the power of fad and suggestion as etiological factors in modern appendicitis it would add to the interest.

In two decades of service on the frontier, associated with commands varying from one company to twelve, and terminating nearly twelve years ago, I encountered one case of appendicitis, and that in a civilian who died under medical treatment.

Since the beginning of the Spanish-American war cases and operations in the army have been many. Personally, I have been interested in but six cases. One patient was treated without operation and recovered. Five were operated upon. Three of these had abscesses, one of the three dying of septicæmia; the other four recovered. Five cases are not enough for a fair average, but the 20 per cent. indicated is only 3 per cent. higher than the mortality reported by the New York surgeon alluded to.

Reaction toward conservatism is not new in abdominal surgery, and we may reasonably expect it in the matter of appendicitis.

S. S. Turner, M.D.,
Cont. Surgeon, U. S. A.
Fort Yates, N. D.

THE SANITARY CONDITION OF NEW ORLEANS.

To the Editor of the Medical Record:

Sir: In reply to your editorial in the issue of February 14, regarding the unclean condition of the streets of the city of New Orleans, I am happy to state that matters have been improved some since the writing in the *New Orleans Medical and Surgical Journal*. However, I am instructed by the Louisiana State Board of Health, now in quarterly session, to inform you that under Act 192 of 1898, creating the State and Muncipal Boards of Health, all local matters of sanitation, etc., are under the jurisdiction of the Local Board of Health. The State Board, therefore, has no power under the law nor the means to compel the municipal authorities to clean up the streets.

The State Board regretted deeply the condition of things more on general principle than from any particular theory, but did not see its way to remedy matters.

The prime duty of the State Board is to prevent the introduction of contagious diseases, specially along the seacoast through maritime quarantine, and the history of its records shows that no infection has come in through any of its ports since the inauguration and perfection of scientific quarantine, *i. e.* disinfection of vessels, nearly twenty years ago.

Edmond Souchon, M.D.,
President Louisiana State Board of Health.
New Orleans, February 17, 1903.

SANITATION IN EGYPT.

To the Editor of the Medical Record:

Sir: Egypt has had a short season this year, and by no means a full one. The causes are not far to seek. The Delhi durbar undoubtedly took many English people to India, who would otherwise have come to Egypt, but the event most instrumental in keeping people away was the existence of cholera here last summer and autumn. Cholera was present throughout the entire Nile valley as far south as Wady Halfa, the railway to the Soudan, That the Soudan Sanitary Department was able to keep it out of the Soudan, testifies highly not only to the efficiency of the Soudan Sanitary Department, but to the authority of the Soudan Government over the Soudanese. The Egyptian does not take kindly to sanitary regulations. He is ultra-conservative and scorns innovations. His fatalism not only makes him feel that sanitary measures are useless, but in addition he fears he may merit Allah's displeasure, by attempting to go counter to his will. For this reason the strongest precautionary notices to the natives are of no use whatever. The only way to make them observe preventive measures, is to render it impossible for them to disobey them. If a water supply is infected it must be obliterated or rendered impossible of access. Wells and pools must be filled up, or if the latter are too large, they must be patrolled. On more than one occasion during the cholera epidemic, it was found necessary to destroy all the vessels used for water in a town or district which was infected. There is no doubt but that cholera is endemic in Egypt. An epidemic, therefore, does not depend so much on the presence of the bacillus as upon its degree of virulence. It was observed in the epidemic last summer, to which 40,000 succumbed, that in the beginning the death rate was rapid and frightful. Cases often died within two or three hours of the first symptoms. As time went on the type became milder and the mortality was not nearly so high. So it would seem that, while vigorous and thorough, preventive measures are of the greatest service, there are also natural causes at work which materially aid in suppressing an epidemic. The most stringent sanitary precautions are being taken in regard to the pilgrimage to Mecca this year, and it is confidently believed that any cholera which may occur can be kept in hand. Of the 40,000 cases which died last summer and autumn, very few were Europeans. Egypt receives the scum from the European shores of the Mediterranean, and the cholera cases among Europeans were practically all from this class.

Cholera is very largely a disease of filth and ignorance. The tourist has very little to fear from it. The disease he has reason to fear is typhoid fever, which does not confine itself to the lower classes, but, as we learn from the newspapers, frequently invades the royal palaces. Everyone knows people who have contracted typhoid fever while traveling in Europe. Cairo is little, if any, worse than the cities of southern Europe. The laity are all careful nowadays about the water they drink, but most people take cold milk in their tea and milk in their coffee which is probably just a little above incubation temperature. In addition to this—in the writer's opinion—butter is deserving of greater suspicion as a source of infection than is usually accorded it. In contradistinction to one's home, in every hotel the food which one eats must necessarily go through a great many hands, and certainly, therefore, be more liable to convey infection.

The Egyptian Medical Congress, which was held in December, proved a highly satisfactory scientific meeting, not only to the resident members, but to the visitors as well. The volume of transactions is in course of preparation, of which each member will receive a copy, and in addition a medal which the Khedive will have struck in commemoration of the event. The next Congress will be held three years hence, and my confrères who want a pleasant and profitable holiday will do well to bear the date in mind. I am yours, etc., C. G. Campbell,

Cairo, March 5, 1903.

OUR ALBANY LETTER.

THE MEDICAL FEATURES OF LEGISLATIVE WORK FOR 1903.

(From Our Special Correspondent.)

Albany, N. Y., April 30, 1903.

The legislative session came to an end, as per schedule previously arranged and announced, and, medically speaking, the sins of omission of the legislators have been greter than those of commission. The Legislature has passed and the Governor has signed the following bills, which have thus become laws, which will be of interest to the medical profession:

Chapter 1.—Senator Ambler's, appropriating $10,000 for the suppression of contagious disease among animals.

Chapter 12.—Assemblyman Allston's, authorizing Little Falls to contract with a hospital for the care of the sick poor.

Chapter 13.—Assemblyman Bostwick's providing that when a child is committed to a public institution, pursuant to law, the justice of any criminal court may order the arrest of the father to ascertain his ability to provide for the child.

Chapter 24.—Assemblyman Roger's, appropriating $70,000 for improvements to the quarantine station at Hoffman's Island.

Chapter 39.—Assemblyman Morgan's, amending the charter of the Brooklyn Eye and Ear Hospital by providing that not less than six nor more than eleven surgeons actively connected with the institution shall be members of its board of directors.

Chapter 40.—Assemblyman Wemple's, relating to the coroner's physician and post-mortem examination in Schenectady county.

Chapter 49.—Senator McEwan's, regulations relating to the Board of Governors of the Albany Hospital.

Chapter 55.—Senator Elsberg's, amending the charter of the Lincoln Hospital and Home of New York City.

Chapter 62.—Senator Townsend's, providing that one year's residence in the State shall make a person admissible to deaf, dump, and blind institutions.

Chapter 75.—Assemblyman Davis's, specifying the mode of appeal from decisions of medical examiners in the National Guard.

Chapter 107.—Senator Malby's, establishing a marine hospital in the Borough of Richmond, New York City.

Chapter 146.—Assemblyman Morgan's, providing for the immediate commitment of insane persons who are dangerously insane.

Chapter 180.—Assemblyman Cook's, providing for the erection of a hospital at West Seneca.

Chapter 207.—Senator McClelland's, authorizing Yonkers to expend $5,000 a year for the sick poor.

Chapter 221.—Assemblymen Conkling's, authorizing the State Commission in Lunacy to appoint a medical inspector at a salary of $3,500.

Besides the above there are several other new laws relating to child labor of more or less interest to members of the medical profession.

The Legislature has likewise passed the following measures, which but require the signature of the Governor to make them laws.

The Nurses' Bill, providing for a State board of examiners (composed exclusively of nurses) to pass on the application of all desiring to be Registered nurses (signed).

Appropriations of about $900,000 additional for the care of the insane (buildings, etc.).

Appropriation of $50,000 for a site for a new State hospital in Northern New York.

Appropriation of $200,000 additional for charitable institutions.

State Barbers' Commission for the sanitary inspection of all barber shops.

Providing that each can or package of adulterated cream or milk, offered for sale, shall constitute a separate violation of the agricultural law.

For the Prevention of the adulteration or misbranding of food or food products.

The Bostwick bill in relation to drugs as prescribed by physicians.

Appropriating $115,000 for the Raybrook Hospital for the treatment of pulmonary tuberculosis.

Health Commissioner Lewis's bill relative to the discharge of sewage and other refuse or waste matters into the waters of this State.

Health Commissioner Lewis's bill to amend the public health law relative to local boards of health.

The Rogers' bill appropriating $100,000 for tuition fees of non-resident high-school pupils, to be distributed under regulations prepared by the Chancellor of the Regents and the State Superintendent of Public Instruction. (The above is a sad makeshift, and shows that the attempt to take the public schools out of the possible contamination of politics has been side-tracked.)

The Elsberg bill, abolishing the office of coroner and substituting medical examiners, failed of final passage. It is stated that this disposal of the bill was meted out as punishment to Elsberg for having been leader of the "insurgents."

The following were elected or appointed:

State Commissioner in Lunacy: Wm. L Parkhurst, to succeed himself.

Medical Visitation Board for Willard State Hospital: Wm. S. MacDonald of Seneca Falls.

Trustees of the Hospital for Incipient Pulmonary Tuberculosis: John Seely Ward and Dr. Willis MacDonald, reappointed.

Regents of the University of the State of New York: Chas. A. Gardiner of New York City to succeed Anson J. Upson and Charles S. Francis of Troy to succeed Martin I. Townsend.

Manager of the State Orthopedic Hospital: J. Hampden Robb, reappointed.

Manager Syracuse Institution for Feeble-minded Children: Fred'k A. Lyman of Syracuse.

Health Officer for the Port of New York: Dr. Alvah H. Doty, reappointed.

ALBUMINURIA AND EGGS.

To the Editor of Medical Record:

Sir: A case of albuminuria, which I believe to be of unusual interest to medical examiners, was recently brought to my attention in making an examination for life insurance. Mr. S——, a young man twenty-six years old, very healthy in appearance and a total abstainer from alcoholics, came to me to be examined. On that day the urine analysis was as follows: Alkaline specific gravity 1025; no sugar and 5¼ per cent. albumin present. Microscopic test negative. On inquiring into his diet for the previous five days, he stated that he had been in the habit of eating four to five eggs, cooked in various ways, every morning, and on the morning of the examination he had eaten six fried eggs. I requested that he abstain from all eggs for a few days and report again. Six examinations at various times of the day for the following three weeks failed to reveal the presence of albumin.

It would seem to be deduced from this case that considerable care should be exercised by medical examiners in cases of simple albuminuria, lest a permanent injustice be done the applicant in obtaining insurance elsewhere, and may account for the great number of rejections for albumin which are later accepted by other companies.

Alfred Lauden Ellis, M.D.

New York, April 20, 1903.

DOGS AND PAVEMENTS.

To the Editor of the Medical Record:

Sir: Your agitation on the subject of dogs and their immodest habits on the sidewalks in our city streets is one which deserves commendation from every thoughtful and self-respecting citizen. The remarks which you quote editorially in your issue of April 4, of the contemporary who said that "perhaps you had put your editorial foot into it," while clever and facetious, yet it is a subject which cannot be passed by lightly. If the same woman who, with her dog on the end of a strap, permits the animal to defile the sidewalk could be brought to understand what endless filth and probable disease she is the cause of spreading, I am sure the nuisance would to a large extent be stopped. On Fifth Avenue, Central Park West, and many of the side streets all over the city, it is actually unsafe for a woman with long skirts to walk after dark. With the curb twelve inches away, it would seem as if dog fanciers of ordinary intelligence would see to it that their pets be trained to better manners. In our homes, where children play on the floors, how easy for the excrement on the street dresses to be spread over the carpets with results far more positive than doubtful. The point is well taken in your issue of April 4, when you say: "If all dogs were healthy the matter might not appear so bad, but for some unknown reason 25 per cent. of city dogs have been found to suffer from diarrhœal trouble." Let those who are devoting themselves to city abuses take up a matter which is certainly on a par with the spitting nuisance, if not far worse. Is it not a subject for serious consideration by the board of health?

Edwin C. Chamberlin, M.D.

5 West Eighty-second Street, New York.

REGISTRATION OF PATENT MEDICINES.

To the Editor of the Medical Record:

Sir: We have some laws more or less contracted in scope, that tend to conserve the public health.

We have laws to control the unscrupulous builder; laws to regulate the insanitary, laws for the seller of explosives, and laws for the "parasitic" doctor, that is to say, he who would practice medicine without first observing the formality of getting a license. But there is no law—and this, in our day, is a strange fact—to protect the foolish public, "born every minute," from the charlatan, who by glaring lithographs and skilful advertising, and portraits of "patients" in Oskaloosa or Kennebunkport, secures credulity to his promises of diagnosis, prognosis and a speedy cure for 67 cents per bottle.

There, of course, exists no public record of the constituents of these "remedies," nor can we tell how ill-suited they may be to the particular disease for which they are employed, and, moreover, there is no knowing what injury to the human economy their usage may cause.

This unrestricted traffic in the public health is simply a gigantic confidence game in which the unfortunate "come-ons" do not get even an ordinary brick.

Now, if we, by law, make the "parasitic" doctor impossible, then why do we permit the "patent" medicine microbe to flourish, for is it not in the same category?

Let us have enacted a law compelling every "patent", medicine vendor to demonstrate the efficacy of his wares, their nature and action, before a board of regular physicians, or our Board of Health, without whose certificate as to the merits of his goods he may not tamper with the public confidence or health. Layman.

New York, April 20, 1903.

REDUCED RATES TO POOR EMPLOYEES.

To the Editor of the Medical Record:

Sir: I beg to say that because of certain misunderstandings as to what is ethically right and proper in the management and the distribution of the cards of an intended worthy charity now being organized by the Rev. Dr. Daniel D. Lorenz of this city (and which errors are not that gentleman's fault), I deem it best to withdraw the use of my name from this scheme for the betterment of certain poor employees of the larger shops of New York. I retain, however, the kindliest of feelings toward that estimable gentleman, Rev. Dr. Lorenz.

Robert H. M Dawbarn, M.D.

105 West Seventy-fourth St., New York, April 28, 1903.

FAILURE OF TETANUS ANTITOXIN.

To the Editor of the Medical Record:

Sir: On page 551 of the Medical Record, for April 4 of this year, I note a report of a case of tetanus unsuccessfully treated by the use of antitetanic serum. Following the citation of that case a brief of a case under my care recently may prove interesting. R. D., on the morning of December 17, shot off the end of the left index finger while manipulating a small gun. Patient was a man seventy-six years old. I amputated finger a little beyond the first joint. Everything progressed favorably until the morning of the 25th, when he woke complaining of a stiffness of the jaws. I feared tetanus and told his wife of my fears.

In conjunction with other treatment, I suggested antitetanic serum. This was objected to at first, but finally, after consultation with other medical gentlemen, the family yielded to my suggestion. From twelve o'clock noon of the 27th to 5 P.M. on the 28th, 220 c.c. of the antitoxin was used with no effect whatever, the patient dying at 8.55 P.M. on the 28th of the month.

The only comment I shall make is simply this: Had the antitoxin been used when I at first wished, there would possibly have been a better chance of favorable results.

W. F. Lynch, M.D.

Elmhurst, Cal.

Progress of Medical Science.

The Boston Medical and Surgical Journal, April 23, 1903.

The Cortical Cell Changes in Epilepsy.—L. Pierce Clark and Thomas P. Prout state that probably the most practical lesson to be drawn from their post-mortem examination of eighteen cases of epilepsy, is that epilepsy is a diffuse lesion of the entire cortex. The ultimate disappearance of the involved cortical cell element is the most serious clinical phase of its pathology. This fact explains many of the permanent symptoms of the disease, especially the slowness, awkwardness and incoördination of muscle movements, which amounts, in many instances, to a paralysis in effect. The mental changes in epilepsy are analogous, if not commensurate, with the defective motility. In this study we have adequate evidence for the present empirical treatment of the disease in which the individual is given first attention. This consists largely in giving the patient a thoroughly detailed plan of diet, exercise, recreation, baths and sedatives comprised in the administration of bromides, in order to overcome hereditary tendencies and exclude toxic and autotoxic agents.

The Reaction Time of Corrosive Sublimate in Different Dilutions against Various Species of Bacteria.—Charles Harrington and Harold Walker conclude from their researches that corrosive sublimate in as weak solution as 1:5,000 is ineffective against the common pathogenic bacteria, including the pus organisms, when they are moist, excepting after prolonged contact. In the 1:1,000 solution it is very slow in its action on some of the commonest of the skin bacteria, and since, under the most favorable conditions, more than ten minutes' contact may be necessary for it to kill staphylococcus pyogenes albus, it should not be relied upon to any great extent to ensure sterility of the hands or of instruments. The mere dipping of the hands for a few seconds into solutions of this strength can serve no useful purpose, but, on the contrary, can lead to much harm by inducing a false sense of security. In order to produce sterility of the hands through the use of this preparation, absolute dryness of the bacteria present would be essential (resistance being greatly diminished in some species by a condition of dryness); but a condition of the skin which would ensure such dryness would also ensure the bacteria not on the very surface against contact with the poison. Corrosive sublimate in any of the strengths commonly employed is a much over-rated disinfectant, and, under the best of conditions, is so uncertain in its action that it would be of advantage to abandon its use altogether in surgery.

New York Medical Journal, April 25, 1903.

Operation in a Case of Extradural Hemorrhage, the Result of Whooping-cough.—G. S. Brown reports a case of this unusual nature, his patient being a boy of seven years. In course of time, severe head pain, somnolence, semi-delirium, slow pulse, and fever came on after severe paroxysms of coughing. Later convulsions ensued. Diagnosis was made of a clot in the right cortical motor area, but on opening the skull no clot was found. The dura was then opened. Two days later convulsions returned and the wound was opened up. A button of bone higher up was removed, and the dura again opened, but with the same negative result; but on cutting away a small corner of bone from the last trephine wound, a small clot was found, the size of a white bean. This was removed, and in two weeks the boy was well.

Fatal Meningitis with Myosis and Salivation as the Only Symptoms.—The history of the case is minutely given by H. Altshul, his patient being a man of fifty-three years. Full autopsy findings are added. From a consideration of all the features in the case, the author concludes: (1) That extensive meningitis can exist without giving rise to its characteristic and usual symptoms. (2) That sepsis does not always cause changes in pulse and temperature, and that their being normal does not warrant our excluding this condition. (3) That a spasmodic and complete occlusion of the ureter, which is not due to impaction of renal calculi, may last for some time and thus prevent the detection of extensive pyonephrosis. (4) That myosis and salivary suppression may be the first symptoms of meningitis or myelitis. (5) That reasoning by exclusion will enable us to arrive at diagnoses otherwise impossible of attainment.

Journal of American Medical Association, April 25, 1903.

The Use of a Mydriatic after the Age of Forty-five Years.—From a collective investigation on this subject H. M. Starkey concludes that no age can be arbitrarily fixed beyond which cycloplegics must not be used, and while they are as necessary in certain cases after forty-five as they are before, they are required in fewer and fewer cases as life advances. But since there is more danger of glaucoma in the elderly, and as mydriatics tend to increase intraocular tension, these drugs should be used with caution after the age of forty, and in certain cases should not be used at all.

Oblique Inguinal Hernia.—The operation preferred by A. E. Benjamin is thus described: An ordinary incision for a Bassini operation is made. The aponeurosis of the external oblique is slit up to the point opposite the internal ring. The fibers of the internal oblique and transversalis muscles are divided by blunt dissection, thus opening the inguinal canal. The internal oblique and transversalis muscles are found closely connected. They are not separated, but the aponeurosis of the external oblique is carefully and thoroughly removed from the internal oblique. The lower portion is dissected down to Poupart's ligament and the transversalis separated from the peritoneum. The cord is now raised and silkworm-gut sutures are introduced to the outer side of the incision, passing through the skin, Poupart's ligament, the internal oblique and transversalis, on the inner side of which the loop is made. The needle, re-entering the transversalis and internal oblique, passes through Poupart's ligament and comes out through the skin to the outer and lower side of the cut, near the point of entrance. From three to five sutures are similarly introduced. The sutures pull the internal oblique and transversalis below the shelving edge of Poupart's ligament, and are observed to make a firm barrier against any internal force. A double support is formed and any defect is corrected. The sutures are then tied over rolls of sterilized gauze. The spermatic cord then rests on the internal oblique. The external oblique is then closed over the cord. Interrupted figure-of-eight sutures are introduced, bringing the external oblique in apposition with Poupart's ligament. They also approximate the skin, and are tied over a gauze roll. The sutures are usually left two weeks.

Medical News, April 25, 1903.

Hydragogin—Some Observations upon Its Use in Diseases of the Heart and Kidneys.—M. Loewenthal says that in this remedy we have undoubtedly a great addition to the list of cardiac stimulants. For functional derangements, like palpitation, there is nothing superior to it. It has a particular effect to increase the power of the heart's contraction in a more regular and uniform, though not in so powerful, a manner as does digitalis alone. But in increasing the specific gravity of the urine in chronic Bright's disease the power of hydragogin is much greater than that of digitalis. In severe cases of acute diseases are seen the most marked illustrations of the advantage of the combined action of cardiac remedies as presented in hydragogin. Patients vary as to their tolerance of the drug. The diet should consist only of milk and water while hydragogin is being given.

Report of a Case of Monocular Inferior Hemianopsia.—E. S. Saylor reports the case of a woman of seventy-seven years. She had always been well, with the exception of a marked tendency to faint and several severe attacks of rheumatism. She began to experience defects of vision. Examination showed monocular inferior hemianopsia. The first thought was of embolism of the superior branch of the central artery of the retina and detachment of the same. But there were no signs of either of these. Cortical disease was out of the question, owing to the regularity of the limiting line below, the trouble being in only one eye, and the fact that there was no reaction of the pupil when throwing a minute ray of light on the blind half of the retina. The writer finally concluded that it must be a retrobulbar neuritis of rheumatic origin and so gave the salicylates. The vision rose rapidly from $\frac{2}{200}$ to $\frac{5}{12}$. The field increased very markedly also. Later, hydriotic acid and strychnine were ordered, and the refractive error corrected. Vision $\frac{5}{6}$ was obtained.

The Treatment of Acute Gout.—J. R. Clemens writes that in a diagnosis of acute gout we must take into consideration: The sex of the patient, the age, heredity, and the physical signs of the gouty diathesis. Acute gout is much commoner in men than in women. It is rarely seen before the third decade of life. A gouty family history is an important point to ascertain. A cathartic should be given first, blue pill followed by black draught. After

this has acted well, the following mixture should be taken every three hours (in doses of two tablespoonfuls) till the motions become very free, when the time between doses may be increased: Magnesii sulphatis, ʒiss, magnesii carbonatis gr. xxx, potassii citratis gr. xxx, tinct. sem. colchici, ℥x, aquæ. menth. pip. ad ℥i. The local treatment of the joint is most important. It should consist in *warmth*. This is the one essential and all important. Cold applications should never be applied to a gouty joint. For the first day or two the diet should be milk in various forms. During convalescence the joint, when pain-free, should be gently massaged. The urine should be carefully watched.

American Medicine, April 25, 1903.

Glycosuria Gravidarum.—William Ruoff concludes that glycosuria gravidarum may arise at any stage of pregnancy. It may disappear in one pregnancy and reappear in another, and end fatally after successive attacks. It frequently arises during parturition, but is of no great importance. Labor is not materially affected, other conditions being equal. Pregnancy is most likely to be interrupted. It is very destructive to the fœtus, more so than syphilis. Maternal mortality is nearly 50 per cent. Diabetics should not marry. Death is usually by coma, no case of eclampsia having ever occurred in a diabetic

A Contribution to the Study of Manubrial Dulness, Especially as Related to Enlarged Bronchial Glands.—H. B. Whitney states that the chief diagnostic importance of bronchial adenopathy lies in its differentiation from aneurysm or mediastinal growth. Pressure symptoms of adenopathy may be very pronounced. In one of the cases reported here there was recurrent paralysis and tracheal stenosis, and in two of the cases, compression of the left bronchus. With such symptoms, diagnosis may, at times, be very difficult. Chief stress must be laid upon occupation and history. In the existence of manubrial dulness the entire absence on the one hand of any sign of aneurysm, and on the other of any suggestion of malignancy, such as cachexia or enlarged cervical glands, should point to the careful investigation of the patients antecedents and the condition of the lungs. Especially with reference to pneumonoconiosis, such as slight consolidation or bronchitis. In most aneurysms, if there is any dulness it is to the right of the median line. The dulness of adenopathy is most often on the left. The dulness of early aneurysm is apt to be small, while that of adenopathy is more apt to be diffuse.

A Study of Weights in Pulmonary Tuberculosis.—Lawrason Brown concludes that: (1) Toxin absorption in the tuberculous area causes reduced assimilation and fever. Loss of weight in all probability due to this. (2) It is not the amount eaten, but the amount assimilated that is of value to the consumptive. (3) Carefully regulated rest and exercise are of most importance as regards the bodily weight in pulmonary tuberculosis. Forced muscular activity is always injurious. (4) Assimilation is often markedly increased by change of residence or of climate. (5) Excessive gain in weight may be injurious. (6) The gain in weight is usually first evident on the chest, next upon the abdomen in men and on the hips in women. (7) A quick, constant, and continuous loss of weight indicates as surely as any other phenomenon that a patient is rapidly losing ground. (8) A gain of a few pounds is of little value in prognosis, but if the gain is constant and continuous over a period of two months, the patient is probably improving. (9) The weight gained affords no sure data for prognosis, but, on the whole, patients who gain over twenty pounds do better than those who gain less. (10) Sunshine and dryness are not necessary factors of gain in weight. Cold weather stimulates assimilation, and gain in weight more than warm.

Philadelphia Medical Journal, April 25, 1903.

Splenic Anæmia; Notes of a Case.—A. L. Benedict reports this case, which has none of the marks of an essential anæmia and, according to Osler, culminates in Banti's disease, with obvious involvement of the liver. The following facts are suggestive: Hepatic sclerosis is practically always associated with some degree of secondary anæmia. Splenic anæmia is limited by definition to a recondite association of anæmia and splenic enlargement, neither of which is explainable by disease of well-known pathology. Osler has shown that hepatic sclerosis is part of the symptom complex in advanced cases of Banti's disease. Splenic anæmia has all the earmarks of a toxæmia. Splenic enlargement is quite characteristic of hepatic sclerosis, though not always found, at least at the time of examination.

The Association of Tabes and Multiple Sclerosis; Report of a Classical Case of Tabes with Intention Tremor and Nystagmus.—Charles J. Aldrich reports the case of a man of fifty-three years who presents a perfect type of intention tremor with nystagmus. The patient is a classical diabetic, yet, in view of the man's age and the fact that we may have nystagmus in locomotor ataxia as well as motor irritations, such as tremor, impulsive movements, athetoid gestures (and why not intention tremor?), the writer sees no necessity of complicating our pathology by assuming the simultaneous existence of the two diseases. We have no definite knowledge of either the character or exact location of a lesion which uniformly and invariably produces intention tremor. If, as Towers states, the two diseases may simultaneously exist in the nervous system as a most rare combination, then this case offers a far greater claim for that distinction, since the symptom group of tabes is classical; and that of multiple sclerosis may at least be mentioned in the plural.

The Lancet, April 18, 1903.

A New Method of Treating Suppurating Catarrh of the Middle Ear.—A. A. Gray dissolves iodoform in anilin in the proportion of 1 to 7. On evaporation the iodoform is deposited in large crystals. Not more than 4 minims should be instilled into the ear at one setting. The remedy should not be used more than twice a week and applications should always be made by the surgeon. The ear should be dried out in the usual manner and granulations removed. Four case-histories are given illustrating the effects of the remedy, which the author has found serviceable in the old, stubborn cases not improving under the usual treatment.

A Case of Acute Trional Poisoning.—A woman aged twenty-nine years, under the care of H. D. Rolleston, took 125 grains of the drug at one dose. When seen two hours and a half later she was found on the floor, unconscious, with pale face, slow and heavy breathing, heartbeats ninety per minute, but no radial pulse. She was given strychnine $\frac{1}{30}$ gr. hypodermically. Soon she began to rouse and vomited. The pupils were at first widely dilated, but as she recovered, somewhat contracted. The stomach was washed out with permanganate solution and later with bicarbonate of soda solution. Purgatives were also given. She gradually improved, and her condition became normal in four days.

Carbolic Acid Poisoning from External Application.—In a patient of J. A. Raubenheimer's, a girl of six years, with genu valgum, the leg was cleansed for operation in the usual manner and wrapped in towels wet with a 1-40 carbolic solution. Two hours later she was discovered to be unconscious with dilated pupils and rapid, feeble pulse. Stimulation was immediately begun, and towels removed Some urine was drawn, but showed no carboluria. Two hours and a half later she began to recover consciousness and vomited, but nothing peculiar could be detected in the vomit. Another specimen of urine was then obtained, of a pale green color and becoming darker on exposure to light and air. This responded to the usual test for carboluria, as did all the urine passed for the ensuing twenty-four hours. The child recovered completely.

Narcotile Bichloride of Methyl-ethylene.—T. Eastham gives outline notes of his results with the administration of this remedy as a general anæsthetic. Narcotile is stated to be a pure and definite ether obtained by the direct reaction of hydrochloric ether on mixed ethylic and methylic alcohols distilled together. The vapors are condensed under pressure and purified. It is transparent and colorless with an agreeable odor, but highly inflammable. A special apparatus for its administration is figured. The effects in general resemble those of ether. After a few inspirations, the air-valve of the inhaler is closed, so that the patient breathes only the saturated narcotile vapor. No shock or collapse have ever been noted. An extremely useful sign of commencing anæsthesia is the loss of the lines and ridges above the nose, due to the relaxation of the occipitofrontalis muscle. By thus watching the facial ridges the eye need never be touched before consciousness is lost. In the eye, it is noted that the pupils at first dilate, but soon become smaller, and often markedly contracted. The conjunctival and light reflexes disappear. If more narcotile be given, the pupils dilate and the eyelids separate, showing that too much of the anæsthetic is being given. The anæsthesia is rapid. The recovery is remarkable on account of its extreme rapidity, and is usually unaccompanied by headache, giddiness, or other unpleasant symptoms. Soon after the patients "come to" they can express themselves clearly. If the operation is commenced before the patient is anæsthetized the patient is usually in a semi-conscious state and knows what is taking place—hears and feels external objects. If the narcotile is increased the patient becomes insensible to pain and yet sees and knows what is going on around him, but if the narcotile is further increased its anæsthetic properties are as efficacious as those of ether or chloroform. The symp-

toms of an overdose are separation of the eyelids with dilatation of the pupils and shallow breathing. After-effects are headache and vomiting, but they pass off quickly.

British Medical Journal, April 18, 1903.

Rhythmical Compression of the Chest in Infantile Capillary Bronchitis.—T. Houghton Mitchell reports the case of a child of six weeks, suffering from capillary bronchitis. He placed the child in a sitting position on his knee with the head thrown well back over one arm, and then commenced steady rhythmical compression of the chest with one hand. The treatment is a combination of artificial respiration and "lung massage." The inflammatory products are thus pressed out from the lungs. It also causes peripheral irritation of the lung tissue, and consequent reflex vaso-motor effects in it, which promotes its circulation and the elimination of its morbid products.

A Clinical Lecture on a Fifth Series of Cases of Total Extirpation of the Prostate for Radical Cure of Enlargement of that Organ.—P. J. Freyer has, in this and previous lectures, given full details of thirty-one instances of complete removal of the prostate performed by himself within about two years. The ages varied from fifty-eight to seventy-nine years, the prostates weighing from one and one-half to ten and one-quarter ounces. A very large proportion of the patients were almost moribund before the operation. Scarcely any of them were free from one or more grave complications. Of these, twenty-seven were successful, both immediate and remote. There has been no relapse. There were four deaths in connection with the operation. In only one case can death be possibly attributed thereto.

An Address on Gastric Hyperacidity (Hyperchlorhydria); Its Nature, Diagnosis, and Treatment.—William Russell states that in recent years it has been recognized that there is a gastric hyperacidity which is due, not to the fermentation of foodstuffs in the stomach, but to a true excess in the amount of the special acid normally secreted by the organ. This condition is termed hyperchlorhydria. Discomfort does not begin till during the forenoon. The pain lasts an hour or two and may pass off to reappear after midday. The pain is usually referred to the epigastrium. Other symptoms are flatulent distension, gaseous eructations, heartburn, and acid eructations. In severe cases there are physical and mental exhaustion. The over-secretion is more a chemical and a diathetic error than a neurosis. Treatment depends upon the severity and the history of the case If the case is mild and associated with constipation, the correction of this may be sufficient. In other cases, an alkali taken some time before food helps greatly. Diet depends upon the severity of the symptoms. The proteids ought to be so selected and cooked as to be easy and ready of digestion. The starches should be as much altered as possible. The quantity of food should not exceed the physiological requirements.

Note upon a Possible Relationship between Carcinoma and Nerve or Trophic Areas.—G. Lenthal Cheatle states that he wishes to point out certain features in the pathology of cancer when it is viewed stripped of the masking effects produced by the presence of secondary deposits. First, there is a proportion of cases which show a marked relationship between the spread of the primary focus and the distribution of nerves and trophic areas. The extent of these areas should be taken into consideration in marking out incisions when removal of cancer is contemplated. The writer does not detract from the importance of the lymphatic pathways of distribution. He simply adds another factor. Second, there is reason for thinking that the incidence of cancer within a nerve area is not a fortuitous circumstance, but that it may be due to the direct or indirect nervous influence over that area. Irritation is a great precursor of cancer, and it causes degeneration in the particular ganglia the peripheral ramifications of which are irritated. The writer does not claim to enunciate a new theory of cancer but to show that there is reason to consider the possibility that the genesis and spread of cancer may be connected directly or indirectly with the nerve influences which preside over the areas affected.

Berliner klinische Wochenschrift, March 30, 1903.

The Hetol Treatment of Tuberculosis.—Sigismund Cohn reports fourteen cases and denounces the treatment. None were cured, one was improved, seven remained unchanged, five grew worse, and one died. In every case the diagnosis was established by a microscopical examination of the sputum and the clinical picture. The hetol was in all cases given by intravenous injection into the median vein. Three inoculations were given weekly, the dose varying from .0005 to .009 gr. No other treatment was given, but in every case the nutrition was kept at the highest possible standard.

Barlow's Disease.—O. Heubner considers this disease in its entirety on the basis of sixty-five cases which came under his observation from 1876 to 1903. Of these thirty-five occurred in 1901 and 1902. Of these sixty-five patients thirty-nine were boys and twenty-six girls. The age at the beginning of the sickness varied from five to fifteen months. All were bottle fed and in every case the food mixtures used were cooked for a longer or shorter time previous to administration. The majority were private patients and belonged to the better classes of society. Forty-four showed the characteristic lesions of the gums and in twenty-one they were absent. In six of the latter, however, hemorrhages occurred in other regions of the body, such as the kidneys, skin, etc. Fifty-four cases showed the typical bony swellings of the lower limbs; thirty-three times in the thigh alone, seven times in the leg alone and fourteen times in both the thigh and leg. Six cases showed, in addition to the above, bony swellings of the skull. In six cases there was a hemorrhagic nephritis, and in thirteen hemorrhages in the skin and mucous membranes. Nineteen cases showed pronounced symptoms of rachitis. This small proportion speaks against the view that Barlow's disease is essentially a rachitis, as has been claimed by many. Pathologically, the disease is to be regarded as a nutritional disturbance of the bony tissues, with an especial tendency to hemorrhage. The prognosis is favorable, provided the proper treatment is instituted. This merely consists of the administration of uncooked food. No medicine whatsoever is necessary. The early diagnosis of the condition is of the utmost importance, for if a diet of cooked food is continued a fatal termination usually ensues.

Berliner klinische Wochenschrift, April 6, 1903.

Significance and Relation of the Splashing Sound to Atony of the Stomach and Gastrectasia.—Paul Cohnheim, from a review of the literature and his personal observations, does not believe that the splashing sound is diagnostic of atony of the stomach. While it is true that it is found wherever gastric atony is present, it is also true that it may be present without atony. It is often heard in cases of gastric neurasthenia where no atony is present. Except following pregnancy or rapid emaciation from various causes, it is a sign of asthenia universalis congenita, and is to be regarded as a danger signal of gastric atony.

Estimation of the Urinary Pigment and Its Diagnostic Importance.—G. Klemperer believes that estimations of the amount of urochrome present in the urine are of value in determining the functional activity of the kidneys. Recent observations have shown that urochrome is formed in the kidney from the blood pigments, and it seems certain that the amount of urochrome so formed bears a direct relation to the activity of the organ. Klemperer estimates the amount of urochrome present by treating the urine according to a modification of Garrod's process, in that the pigment is first extracted with animal charcoal. The author shows that in individuals not suffering with renal lesions the percentage of urochrome varies from .8 per cent. to 2.7 per cent. In reduced renal activity, on the other hand, the percentage is much lower, often reaching 3 per cent. to .4 per cent. For practical use complicated tests are not necessary, and it is important only to remember that when the amount of the urine is reduced, its color should increase in intensity so that, with a small amount of urine, its grade of color shows the amount of kidney damage—in other words, the lighter a scanty urine, the more the renal involvement.

Deutsche medicinische Wochenschrift, March 26, 1903.

Excretion of Volatile Fatty Acids in the Urine.—Fritz Rosenfeld says that the excretion of volatile fatty acids in the urine is increased in gastric ulcer and gastrectasia with hyper- or normal acidity. The same acids are reduced in amount in atonic conditions of the stomach with reduced acidity and which are due to an old pylorus cicatrix or gastroptosis. In gastric carcinoma with reduced acidity the fatty acids are also increased in the urine and the explanation is probably to be sought in the lowered oxidating powers of the body due to the reduced vitality which is present in this disease.

Pulsating Shaking of the Head (Musset's Symptoms).—B. Herzog recalls this symptom and reviews the literature. It has been especially observed in connection with aneurisms and hypertrophy of the left ventricle, and is supposed to be caused by increased arterial pressure. It is, however, also frequently observed in conditions such as syphilis, nephritis, chronic alcoholism, etc., which are accompanied by atheroma of the arteries, and it is certain that the symptoms may be causd by such changes in the arterial walls, as produce inequalities of the blood current. The symptom is not, therefore, in any sense diagnostic of aortic aneurysm.

Deutsche medicinische Wochenschrift, April 2, 1903.

Abscess of the Cerebellum with Sudden Paralysis of the Respiratory Center.—H. Fleiss reports the case of a man thirty years of age who had suffered from a purulent discharge of the left ear since early childhood. He was suddenly seized with a left-sided facial paralysis, which was shortly followed by vomiting, pain in the right side of the head, and other symptoms of cerebral abscess. Marked rigidity of the neck muscles appeared, and trephining was resorted to. Ether narcosis was employed, but after a very few inspirations had been taken there occurred a sudden paralysis of the respiratory center and death. Upon autopsy there was found an abscess of the anterior external quadrant of the cerebellum. The abscess cavity was 3½ cm. by 3 cm. by 2 cm. The sudden paralysis of respiration was undoubtedly due to the pressure of this abscess upon the respiratory center, which had reduced its activity and made it extremely susceptible to the action of the anæsthetic.

Action of Bismuth.—G. Fuchs does not think that the value of bismuth in the treatment of ulcer of the stomach is entirely due to the mechanical action of the drug, but that it is oxidized in the stomach, and thus a new compound is formed. Calcium carbonate, magnesia, and similar drugs which have the same mechanical action as bismuth, possess no such action over ulcer of the stomach as does the latter drug. The mucus secretion caused by the introduction of bismuth subnitrate into the stomach is not due to a mechanical irritation of the bismuth crystals but to a specific action of this drug and its preparations. Bismuth, when introduced into the stomach, is, after a short time, changed into a bright gray substance, which is equally deposited upon the entire gastric wall. Bismutose appears to be an especially reactive preparation of bismuth. It is best administered suspended in syrup and water every two hours.

Münchener medicinische Wochenschrift, March 31, 1903.

Gonococcus Pneumonia.—Bressel reports an interesting case. The patient, while suffering from gonorrhœa, developed a pneumonia. A microscopical examination of the sputum revealed the presence of many intracellular diplococci, the morphology of which coincided with that of the gonococcus and which decolorized with Gram's stain. Cultures from the peripheral blood also showed the presence of the gonococcus. The patient recovered. So far as is known, this is the only case of pneumonia due to the gonococcus which has been reported.

Eosinophilia in Hydatid Cysts.—J. Sabrazes reports studies upon seven cases. In two of these the diagnosis was made upon a clinical basis and in the others by puncture or extirpation. All of the cases showed a marked eosinophilia, except during periods of fever, when the relative number of eosinophiles fell to normal. In addition to the general eosinophilia there was present a large number of these cells in the tissues surrounding the cyst. The presence of these can be easily demonstrated by a microscopical examination of sections of such tissues. No changes were noticed in the red blood cells. The total hyperleucocytosis varied from 11,160 to 17,360, the latter figures being obtained in a case of multiple cysts of the abdomen. Mast cells were never found. In the diagnosis of hydatid cysts the presence of an eosinophilia is an important factor with reference to not only an increase of these cells in the peripheral blood, but also their abundant presence in the connective tissue surrounding the growth.

Blood Regeneration.—P. Schmidt thinks that basophilic granules and polychromatophilia are signs of blood regeneration. The former arise from the nucleus and the latter from a mixture of the hæmoglobin and the dissolved nuclear substance. This opinion is based upon the following facts: (1) Basophilic granules and polychromatophilia appear principally during convalescence from anæmias at a time when the general condition is much improved. This applies to both toxic and traumatic anæmias. (2) If one produces experimental anæmia in rabbits by the inoculation of blood poisons and after the latter has become diffused in the general circulation ties off an ear, the basophilic granules appear sixteen to eighteen hours later only in the circulating blood and not in that of the tied-off ear. (3) In many cases of experimental anæmia, and also in that of man, all grades of granulation, from the coarsest to the finest are present, often in the same red blood cell. Both of these forms are most abundant during convalescence. (4) The finest granules are usually found near the periphery of the cell. (5) Oftentimes, in experimental anæmia, the granulations are only to be found in the nucleated red blood cells. (6) Basophilic granules and polychromatophilia are physiologically present in the blood of new-born animals and in the embryo in the later stages of development. Normoblasts are also found here. (7) If tartaric or hydrochloric acid are inoculated in large quantities into animals whose blood contains many basophilic granulated red blood cells, there occurs after a few hours a marked reduction in the number of such erythrocytes and a marked increase in polychromatophilia. Since no polychromatophilia develops in similarly inoculated animals whose blood contains no granulated erythrocytes, it is evident that the polychromatophilia is produced by a solution of the basophilic granules. (8) About three-fourths of all basophilic granulated red blood cells are polychromatic. (9) Embryonal blood and that of the red marrow is often markedly polychromatic.

Munchener medicinische Wochenschrift, April 7, 1903.

Diagnosis of Intestinal Occlusion.—Schneiderlin reports a case in which all the typical symptoms of appendicitis were present and which was operated upon, a slightly swollen appendix being found. The symptoms were not relieved following the operation—the temperature continuing and the abdominal pain becoming more diffused. Five days thereafter a second laparotomy was done, the incision being made to the left of the median line. The entire ascending colon was found impacted with fæces. The impaction was relieved and the wound closed. A rapid recovery ensued. It is thus seen that an occlusion of the intestine may cause continued and marked fever, and the importance of an accurate diagnosis of the same is apparent.

Treatment of Anthrax in Man.—Federschmidt advises excision, and reports three cases in which this was practised with exceedingly favorable results, in that immediately following the excision there was a marked fall in the temperature and improvement in the general condition. In all of the three cases the malignant pustule was located upon the face and the neighboring lymphatic glands were not involved. Seven other cases are also reported which were treated by Stadler along expectant lines. Of these five recovered and two died. In the five which recovered, however, the course of the disease was much more prolonged and more severe than in those in which excision was practised. In the latter recovery had taken place in from one to three days after the operation. In the treatment of this disease the involvement of the neighboring lymphatic glands does not negative an operation or render the same useless, since, in any event the excision of the pustule would remove a large number of virulent anthrax bacilli, which, if allowed to remain, might subsequently gain admission to the general circulation and increase the intensity of the infection.

Widal Reaction in Abscess of the Liver.—Megele reports a case of abscess of the liver in which a positive Widal was obtained in a 1 to 40 and 1 to 100 dilution. The patient showed a more or less irregular fever, the clinical symptoms being suspicious of typhoid fever. On the fifteenth and eighteenth days a Widal test was tried, the results being negative. Repeated tests, however, on the twenty-second and thirty-fourth days showed the reaction to be positive in the dilutions above mentioned. A further test on the forty-second day was again negative. The case continued with an irregular temperature and developed septic symptoms. A few days before death jaundice appeared. At autopsy there was found a large abscess in the liver and several smaller ones in the kidneys. The mesenteric glands were enlarged. The mucous membrane of the entire intestinal tract was normal. The spleen was not enlarged. From the abscess pus and mesenteric glands the staphylococcus pyogenes aureus was isolated in pure culture. From the autopsy findings and the entire clinical course it is certain that typhoid infection can be absolutely excluded. The positive Widal was in all probability due to the presence of bile in the blood in small amounts. This later became increased and gave rise to the jaundice noticed.

Adrenalin as a Remedy for Cancer.—G. Mahu reports two cases of cancer in which this remedy was used. The first patient was a man of sixty-four years, with cancer of the tongue. The second was a man of fifty-two years, with an ulcerated tumor just underneath the epiglottis. Applications of adrenalin to the tumors. A third patient was aged sixty-three years with a large epithelioma of the larynx. All of these patients were in bad condition, and already cachectic. The local, and consequently the general, condition were favorably modified by means of a treatment, simple and without danger.—*La Presse Medicale*, April 4, 1903.

Society Reports.

FOURTEENTH INTERNATIONAL MEDICAL CONGRESS.

Held in Madrid, Spain, April 23-30, 1903.

Special Cable Report to the "Medical Record."

GENERAL SESSIONS.

FIRST DAY—THURSDAY, APRIL 23.

THE inaugural session of the Fourteenth International Medical Congress was held in the Teatro Real, in the Plaza Oriente, on Thursday afternoon, April 23. The house was densely crowded, and, in consequence of lack of arrangements in properly seating the delegates and guests, the greatest confusion prevailed, resulting in an indiscriminate rush for seats.

After long delay and several futile efforts on the part of the President of the Congress, order was eventually restored, the roar of conversation finally hushed, and the session was formally opened.

King Don Alphonso XIII, the Queen Mother, and other members of the Court, occupied the royal box.

Other boxes were filled with the families of the nobility, of the foreign ambassadors, and of the officers of the Congress, while seats on the floor of the house and in the galleries were occupied by members and their ladies.

The theater was lavishly decorated with banners, streamers and flowers, presenting a brilliant spectacle. Most of the Spanish ladies and many of the foreigners wore the graceful white mantilla, adding greatly to the animation of the scene. The King was in General's uniform. His slight erect figure and not uncomely boyish face, with the strongly marked Hapsburg chin, contrasted strongly with the gray heads and beards of the world's leaders in medical science.

On the stage were seated the officers of the Congress and the foreign delegates.

Inaugural Address.—Prof. JULIÁN CALLEJA Y SÁNCHEZ, the President of the Congress, delivered the inaugural address, taking as his theme, "The Progress of Medical Science." After welcoming the delegates on behalf of the King and the medical profession of Spain, he reviewed the different advances made in medicine and surgery and their great influences on mankind in alleviating human suffering and decreasing mortality. It was well acknowledged that the great science of hygiene and disease prevention had not only prolonged human life but the average comfort of living had been raised to a correspondingly high level. While no startling or epoch-making discovery had been made within recent years there was, however, a general and promising progress in every line of scientific research. The number of active and earnest workers in every field of inquiry made such a result practically demonstrable. The present trend of the medical mind was in the direction of prophylaxis of disease, the most remarkable indications of which were the valuable contributions to the study of tuberculosis and the institution of the more rational and universally adaptable methods for its prevention and cure.

While much of the progress was due to bacteriology, the purely clinical side of the argument was being quite boldly asserted. It was quite necessary that both studies should be closely related—the theoretical and the practical—as by such means scientific views would be broadened and general progress in every department be more substantial and lasting. The outlook was certainly promising from such a standpoint, as all new discoveries were thus likely to be the more readily applied to actual and practical needs. In concluding, he doubted not that the deliberations of the Congress would in every respect equal in dignity and scope those of any of the former gatherings of that body, and would be of lasting benefit to the thousands of representatives from all countries who were about to contribute their efforts in such directions.

History of Congress Organization.—Dr. ANGEL FERNÁNDEZ-CARO, the Secretary-General of the Congress, followed with a welcoming address to the delegates, in the course of which he detailed the history and importance of congress organization. It was thirty-six years ago, in 1867, that the first congress was held in Paris, and since that time the attendance and importance of the meetings in the different countries had amply vindicated the sound judgment of those leading French physicians of Bordeaux who, in 1865, so successfully initiated the movement. It was amply demonstrated that the International Medical Congress was a firmly established institution and was a part of the advancing civilization of the age. To prove the great progress made in the organization of the body, he reviewed the proceedings of the meetings held in turn at Florence in 1869, Vienna in 1873, Brussels in 1875, Geneva in 1877, Amsterdam in 1879, London in 1881, Copenhagen in 1884, Washington in 1887, Berlin in 1890, Rome in 1894, Moscow in 1897, and Paris in 1900.

Number of Members Present.—In congratulating the Congress on its large and cosmopolitan attendance, he had the pleasure of stating that 5,000 delegates had been already registered, and there were more coming in great numbers by every train. These were apportioned as follows: Germany and Austria, 1,000; France, 825; Great Britain, 235; Russia, 290; Italy, 335; other European countries, 327; United States, 193; South America, 136.

Responses of Delegates.—The presidents of the national committees of the various countries were then presented and spoke briefly in acknowledgment of their introduction. Most of these addresses were given in French. Among the presidents of the National committees were Drs. A. Jacobi of the United States, F. W. Pavy of Great Britain and Ireland, Nothnagel of Austria-Hungary, Bango y Leon of Cuba, Brouardel of France, W. Roth of Russia, Mörner of Sweden, Schönberg of Norway, Liceaga of Mexico, Barcelli of Italy, Kocher of Switzerland, Violi of Turkey, Bloch of Denmark, Van Bambeke of Belgium, and Da Costa of Portugal.

The United States Committee Accidentally Ignored.—By an unaccountable misunderstanding on the part of the officials having the matter in charge, the delegation from the United States was not only not represented in these responses, but was denied admission to the stage.

Address of Prime Minister of Spain.—Prime Minister SILVELA next followed with an address of welcome on behalf of the State. He was proud of the opportunity of extending the hand of fellowship to the representatives of the progressive scientific thought of the world. The good works of these men were so well known in Spain that he could welcome them as friends. Their discoveries had assuaged suffering everywhere, and their science being essentially humane was productive of happiness and well-being to all. Every other science of morals, politics, and law eagerly sought the aid of medicine. The congresses of the present day, representing as they did the selective thought of civilized countries, took the place of the universities of old, and exerted an influence for widespread good which was in keeping with the grand aims of a glorious calling.

At the close of his address, Silvela, in the name of the King, declared the Fourteenth International Medical Congress duly open.

Reception by the King.—On Friday afternoon, April 24, King Don Alphonso gave a reception to the members of the congress at the Royal Palace. The members from each nation were introduced by their respective ambassadors. The occasion was a brilliant one and was well attended by the delegates and their ladies, and was marked by an enjoyable concert and a buffet supper.

SECOND DAY—SATURDAY, APRIL 25.

The second general session was held on Saturday afternoon, April 25, in the Ampitheater of the Medical School.

but as no previous public announcement had been made of the time or place of meeting, there was a comparatively small attendance.

General Addresses.—The proceedings were opened by an address by Prof Arthur Thomson of Oxford, on "The attitude of the medical profession toward anthropology." (vide page 681)

Dr. Émil R. Coni of Buenos Ayres delivered an address on "The Anti-tuberculosis Campaign in Latin America." (vide page 690), followed by Prof. Wilhelm Waldeyer of Berlin, who spoke on the "Phylogenetic Theories and Darwinism," in which he repeated and amplified his well-known views on the subject of cell survival and natural immunity.

Dr. B. S. Laache of Christiania, Norway, gave the closing address of the session, taking for his topic "Reciprocity in Pathology" (vide page 687).

THIRD DAY—MONDAY, APRIL 27.

Immunization of the Human Organism against Tuberculosis.—The third general session was opened by an address "On the Immunization of the Organism against Tuberculosis," by Eduardo Maragliano of Genoa. The orator contended that there was present in most individuals a natural immunity against tuberculosis, which was amply explained by the fact that all persons exposed to infection did not take the disease. The explanation for this non-susceptibility was to be found in a general sense in the degree of vital resistance of the individual exposed. There was developed in such persons an element of protection capable of counteracting and overcoming the toxic effects of the invading malady. This condition of resistance was only trustworthy when the subject was in good health, as any departure from such a standard by lowering the vital strength rendered infection possible. This point he had amply proved by animal experimentation, which showed the real danger of unhygienic surroundings, particularly among the poor in tenement districts.

In fact, anything that tended to lower the health tone of the body was dangerous in such respects, as was frequently noted during recoveries from ordinary attacks of sickness. The main hope in checking the spread of tuberculosis was in the careful cultivation and proper maintenance of this resisting quality, and not in the multiplication of sanatoria. The sanatoria attacked the disease at its wrong end, for if immunity were perfect there would be no need of such institutions. The main problem centered in this question of immunity. He had been working for a long time with such an end in view, and had given much thought and labor to the production of a serum obtained from immunized animals, by which such protection might be reasonably assured in a passive and contributory way, at least. He believed that he had made some progress in such directions, in such cases at least in which passive immunity might be induced, although active immunity was, of course, much more desirable. The serum could be used hypodermically or taken by the mouth. His experiments on animals had been quite satisfactory from this point of view, and he was encouraged to apply similar methods to the human subject.

Food Adulteration.—Prof. P. Brouardel of Paris delivered an address on food adulteration, in which he condemned sophistications of every kind, and urged the importance of their radical abolishment. Food as food could not be improved. The very existence and survival of the race depended on the maintenance of its absolute purity. No substance added to it, which was not a food in itself, could ever increase its efficiency. Adulteration in any shape meant either danger to health or life. All preservatives were cheats and snares. In many cases the ingredients used for such a purpose were actually poisonous even in small and repeated doses.

He contended that there was not enough attention given to the subject of food poisoning. In one way or another, the effects were easily demonstrable. This was particularly the case when several members of a family were seized with similar symptoms after partaking of the same viands. Under such circumstances it was the duty of the physician to satisfy himself that no adulterants had been used either in food or drink. Salicylic acid was the most common preservative, and in small and frequent doses was not only a frequent cause of indigestion, but was sometimes actively poisonous to infants and aged people. He concluded by urging the enactment of stringent laws against the crime.

Ocular Affections in a Hot Country.—Dr. Juán Santos Fernandez of Havana discoursed on the ocular affections in Cuba as compared with those of temperate and cold climates. Beginning with the eyelids, he stated that he had met with blepharitis but rarely; and in the rarity of scrofula in Cuba he found the explanation of the infrequency of this local expression of constitutional disease. On the other hand, the anæmia, and consequent lack of tone in the tissues prevailing in Cuba as in other hot climates, he found frequently provocative of hordeolum and chalazion. Of the parasitic affections, he said that diseases of the conjunctiva and orbit, caused by the filaria of medina, were common among negroes recently arrived from Africa; and one case had come under his observation in which the filaria oculi humani was found in the corpus vitreum; and in a second case, the parasite occupied the anterior chamber. The nigua chique (pulex penetrans), a common factor in palpebral disease at the time of the Spanish conquest, had been in his experience but rarely met with of latter years. Of the conjunctival affections, he had found purulent ophthalmia of the newborn, even when caused by the gonococcus, more benign in Cuba than elsewhere. On the other hand, blennorrhagic ophthalmia in the adult exhibited a virulence which made it well-nigh impossible to save the eye even with the most careful treatment. An interesting account was given by the author of an acute form of conjunctivitis called by the common people ceguera (blindness). This affection, occurring as an epidemic in the country and in small villages, and affecting children most frequently, was described as characterized by redness and tumefaction of the palpebral and ocular conjunctiva, pain, photophobia—giving rise to exaggerated blepharospasm—excessive lacrymation and abundant mucopurulent secretion, from which the bacillus of Weeks and the diplococcus of Morax might be isolated. The condition was found to be frequently complicated with gonorrhœal ophthalmia, owing to the filthy custom among the common people of bathing a diseased eye with the urine of another individual. Predisposing conditions were found in granular affections of the eye; a previous attack also increasing susceptibility to the malady. Propagation of the disease occurred through a small insect, adiptera, called by the natives "guassasa," and faulty hygiene enters into the question of the spreading of an epidemic as well. The prognosis was good, unless complications supervene. In an experience of twenty-eight years, Fernandez had found trachoma to be rare in Cuba; he stated, however, that its infrequency might be attributable to the special immunity which negroes exhibited toward the disease, these making up a large part of the population. The benignity of the affection in that country he attributed to the open air life of necessity led by the people. In the treatment of trachoma, aside from the usual medical and surgical measures, he had found jequirity serviceable. Among the diseases of the cornea, leucoma had most frequently come under his observation, this being generally due to keratitis, though it was seen as an after-effect of variola. In interstitial keratitis, Fernandez had found calomel, internally, supplemented by warm applications, of great value, and he had recently used subconjunctival injections of bichloride of mercury in this condition with good effect

He had found that the tears evaporate more rapidly in hot climates, so that the lacrymal passages might be, at

times, entirely deprived of them; and a marked preponderance, among the whites, of diseases of the lacrymal passages had been noted; anatomical studies carried out by the author having shown that the comparative immunity to such affections enjoyed by the negro was due mainly to the greater breadth of the nasal duct and consequent more generous size of its orifices; thus rendering occlusion infrequent. The author stated that the iris was generally found to be pigmented in those born and raised in a hot climate, this being a provision of nature to protect the eye from the sun's rays, the effect of the latter being more painful to those in whom the iris was not pigmented, as also to those in whom the eyelashes were poorly developed. Of the diseases of the iris, iritis, both syphilitic and rheumatic were most common. Contrary to the common belief, neither cataract nor glaucoma have been found to be more frequent in Cuba than elsewhere, and Fernandez's experience had proven that ocular affections, due to tobacco, did not exceed, if equal, those produced by alcohol; the comparative rarity of amblyopia nicotiniana being due to the fact that the Cubans were not excessive smokers, and that Havanna tobacco contained less nicotine than that of other countries. Of the ocular affections due to malaria, the author had seen hemorrhage of the retina, and optic neuritis, and in extremely malarious sections of the island, iritis and keratitis of malarial origin, had been observed. The excessive use of quinine in the treatment of paludism had lead to amaurosis of varying degree and duration, but the prognosis in such cases was usually good. In the early stages of yellow fever, Fernandez had seen various congestive affections of the eye, and later, when secondary infections set in, phlegmon of the eyelid, suppurative keratitis, sloughing of the cornea and panophthalmitis had been observed.

Pharmacological Complexity in the Medical Prescription.—Dr. José M. Carracido of Madrid gave an address on this subject, in which he said, in part, that all medicaments acted directly or indirectly upon the albuminous elements of the body, and that while little had been definitely known concerning their mode of action, there was much to indicate that this was in the nature of chemical reaction. In support of this idea, he cited the special affinity of certain coloring substances used in microscopical specimens, for some cells, while others remained unstained; and compared this to the selective action of each therapeutic agent toward given histological elements. He stated, however, that the complex composition of the proteid materials, upon which the mechanism of the organic functions depended, necessitated more complex reagents than those used in the laboratory in general chemistry. The simplicity of the production of lead and copper oxide by heating those metals in the air was contrasted by the author with the more complicated processes of organic chemistry; as, for example, the series of reactions essential to the production of ethylic alcohol by oxidation of ethane; the composite reagents (Millon's, Axenfeld's, etc.), necessary to the characteristic color reactions of albuminous substances. The author held that if such reagents were essential to the modification of dead matter, they were still more necessary to the modification of the complex, living albuminous materials; and that just as the delicacy of reactions in organic chemistry required the association of reagents, each of which modified and attenuated the effect of the other, so in therapeutical remedies the association of coadjuvants and correctives with the basic chemical substance was essential.

FOURTH DAY, TUESDAY, APRIL 28.

The fourth general session of the Congress was opened by an address on

The Plan of the Construction of the Thalamus, by Prof. Ramón y Cajal of Madrid.

The investigations, he said, of Monakow, Gudden, Flechsig, Kölliker, himself, and others had demonstrated that the thalamus was connected with certain sensorial tracts as well as with the visual, sensitive, and acoustic; but it was as yet unknown how this connection was effected—whether these sensorial tracts terminated directly in the thalamic foci or whether the relation was indirect. The investigations, the speaker said, of his brother, confirmed and amplified by his own as well as by those of Kölliker, had certainly proved that the optic nerve terminated by free arborizations in the anterior quadrigeminal tubercle and external geniculate body, but no such demonstration had been made respecting the other afferent sensorial currents, nor was it possible to deduce a plan of construction of the visual foci from what was known of the anatomical constitution of the other thalamic centers.

The speaker's investigations made with the three methods of Nissl, Golgi, and Marchi on the bodies of the smaller mammals (rat, guinea-pig, and cat) enabled him, however, to extend the formula mentioned to all the sensorial tracts, and the conclusions so reached might be summarized as follows:

1. The optic thalamus was a double organ composed of centripetal and centrifugal ganglia. The centripetal or sensorial were; the optic focus or external geniculate body; the acoustic focus or internal geniculate body; the sensitive focus or ventral nucleus (lateral of Kölliker); the accessory sensitive or trigeminal centers, whence arose the central tract of the trigeminus and which were situated respectively in front of and behind the preceding ganglion; the dorsal focus, also sensitive, but of a special sensitiveness was not yet definitely determined; and other less well recognized centers, such as the internal, the median of Luy, the arciform, the raphe, etc., regarding which the speaker investigations were not yet concluded.

The centrifugal or motor intermediary ganglia were: the red nucleus, the body of Luys, the black substance, the subsensitive focus (recently discovered by the speaker), and other gray accumulations of less importance. In this category belonged, also, in all probability, the ganglion of the trabenula.

2. The sensorial or centripetal foci were characterized anatomically by being intermediary stations between the afferent and the efferent or superior tracts. In all these there existed therefore: *a*, sensorial or branching afferent fibers contained wholly within the thickness of the ganglion; *b*, nerve cells, with short axon, of small size and notably downy exterior; *c*, nerve cells, with long axon, forming plexuses and whose axis cylinder entered into the thalamic radiations to give origin to the cortical thalamic or efferent tract; *d*, cerebral or cortico-thalamic fibers, which, descending to the thalamus, anastomosed extensively with its radiations in various cellular plexuses. Each plexus of the visual focus or external geniculate body, of the auditory focus or internal geniculate body, of the ventral or sensitive focus, etc., consisted of a close interweaving of afferent and efferent arborizations within the meshes of which were the nerve corpuscles giving origin to the thalamo-cortical tract.

3. The direct tracts from the primary foci to the cerebral cortex, assumed by Held for the external lemniscus or acoustic tract and by Hösel, Flechsig, and others for the sensitive tract, did not exist. All the fibers of the internal lemniscus or band of Reil terminate therefore in the ventral focus of the thalamus, and all those from the exterior or long arm of the external lemniscus, or auditory tract, end definitely in the internal geniculate body. In the same way the fibers of the central trigeminal tract sent forth collaterals and terminals for the accessory or semilunar sensitive foci.

4. The especially sensitive (not olfactory) nature of the dorsal focus was shown by a study of the afferent or peripheral tract of this center. This was, as is known, the bundle of Vicq d'Azyr, arising by successive divisions (according to the speaker's discoveries) of a common trunk with the fasciculus of the catota. Now the mam-

millary foci where were the neurons of origin of this trunk formed the termination of a large sensitive tract, the mammillary peduncle, erroneously regarded up to the present by Kölliker and others as a descending fasciculus. The author's observations had proved, moreover that the free arborizations of this peduncle terminated in both mammillary nuclei.

5. The physiological function of the centrifugal or cortico-thalamic fibers was up to the present unknown. In order to explain its mode of action we might have recourse to the same hypotheses as those formulated regarding the office of the centrifugal conductors of the retina:—(Fibers of expectant attention, conductors designed to effect an adjustment of the neuronic articulations, agents of cerebral discharge to the thalamic foci to intensify the afferent current, etc.)

6. The centrifugal foci had no peripheral or sensitive afferent fibers and no thalamo-cortical or central tracts. Up to the present the speaker's investigations of the focus of Luys, the substantia nigra, etc., had led him to find in them two essential factors: *a*, Collateral or terminal fibers separated from the cerebral peduncle and internal capsule and forming arborizations in the interior of the same; *b*, Cellules with long axon, the extension of which is in a descending direction to terminate probably in the last motor foci or in the red nucleus which was likewise a motor focus. The so-called lenticular fasciculus of Forel and the area of the same name were only a robust system of collaterals of the motor tract destined to the red nucleus and perhaps to the motor ganglia of the facialis and the ocular muscles.

7. The centripetal and centrifugal foci were arranged in general in a definite order. With the exception of the ganglion of the trabenula, a centrifugal ganglion which was situated superiorly, all the intermediary motor nuclei were subthalamic, and the centripetal or sensorial were superior, constituting the thalamus properly called.

Prophylactic and Therapeutic Indications in Tuberculosis.—Dr. Albert Robin followed with an address on the prophylactic and therapeutic indications in tuberculosis founded on the knowledge of the individual in which the disease develops. The argument was in favor of treating the patient rather than the disease. The infecting bacillus was of little account if a receptive soil for the seed did not exist in the subject. He believed that the proper way to combat tuberculosis was by supporting the patient against chance infections. Whatever was wanting or defective in nutrition should be supplied. It was in this way that nature could be aided in her attempts to throw off the disease. The patient first, and the bacillus afterward.

Award of Prizes.—The Moscow Prize for original research by the City of Moscow, in honor of the meeting of the Congress in that city in 1897, was awarded to Professor Metchnikoff, and that of Paris to Professor Grassi.

At the close of the general session the representatives of the different nations delivered addresses and indulged in the mutual congratulations usual on such occasions.

Notwithstanding these pleasant interchanges of courtesy, between the committees of the Congress and their guests, it must be acknowledged that there was an utter lack of systematic arrangements for the meetings. They were held in out-of-the-way places, were not properly announced, and consequently were very poorly attended. No one seemed empowered to give any information regarding what was to be done or how it was to be done. The committees were even more confused than the delegates. The result was that the greatest confusion prevailed during the entire session, resulting in the omission from the program of some of the most important addresses. Thus Politzer, Pavloff, and others were not heard.

The next place of meeting will probably be Budapest.

ENTERTAINMENTS AND FESTIVITIES.

The social and festive side of the Congress was so far from being neglected as almost to throw the scientific aspect of the gathering into the shade. The entertainments began with the Medical Press Congress, which was held on the Monday, Tuesday, and Wednesday preceding the great Congress. On Monday evening the medical journalists were given a general reception at the house of President Señor Cortezo. On Tuesday afternoon a Basque ball game was given in their honor at the Trontón Central, and in the evening they were entertained at a reception given by Madrid political Press. On Wednesday there was a breakfast in their honor at half-past twelve, a reception by the City Council at six, and a theatrical performance at nine o'clock.

On Thursday, the opening day of the International Congress, there was a reception to the congressists by the City Council of Madrid, and, in addition, many of the prominent members were entertained at the private residences of Madrid physicians. On Friday, the 24th of April, the King granted an audience to the members of the Congress, in the Royal Palace, at three o'clock. On the following evening, April 25, at ten o'clock, a grand reception was given in the offices of the Minister of State by the Spanish Government. On Tuesday afternoon a grand concert was given in the Jardines del Buen Retiro. On Wednesday, from 4 to 6 in the afternoon, a garden party was given in the Campo del Moro, or gardens of the Royal Palace, the Infanta Isabel receiving in place of the Queen Mother, who is still in mourning. In the evening of this same day a banquet with 200 covers was given in honor of the congressists in the Casa de la Villa. In addition to these general entertainments, all day and every evening private excursions, receptions, and dinners were given to this or that group of congressists.

Señor Julián Calleja, the President of the Congress, gave a banquet to the presidents of the various sections and of the national and international committees, and most of the sections had special dinners on one of the least full of the evenings of the week.

A special theatrical performance was given in honor of the Congress, the middle of Congress week. On every afternoon during the week Mrs. Arthur Sherburne Hardy, wife of the United States Minister to Spain, was at home to the American members and the ladies of their families.

Syphilis as a Cause of Chorea.—L. Harrison Mettler thus formulates his conclusions: Syphilis, in rare instance, is a cause of chorea, and it should always be thought of as a possibility during the examination of every case. Chorea may be the result of acquired or hereditary syphilis. Most of the cases of syphilitic chorea are unilateral, though they may be bilateral and generalized; may belong to the pre- or posthemiplegic type of the disease; may or may not be associated with other signs of an irritative lesion; may not infrequently be developed in hereditary syphilitics, and are to be attributed in all probability to a functional disturbance of an irritative sort in the cortical and ganglionic motor cells. The fact that there are two forms of syphilitic chorea, the focal and the diffuse, supports the inference that all forms of chorea are but the expression of one or more of a multiplicity of possible factors which may disturb the functional activity of the upper motor neurones, these factors being all the way from a gross lesion down to a molecular or chemical change not demonstrable with our present methods of investigation. This leads to the conclusion that chorea is not a disease but a mere symptom. Syphilis having been settled upon as the cause of any particular case of chorea, that case should be regarded and promptly treated as a case of syphilis, and not as one of chorea.—*The Chicago Medical Recorder*, March 15, 1903.

Books Received.

The Diagnosis and Modern Treatment of Pulmonary Consumption. With Special Reference to the Early Recognition and the Permanent Arrest of the Disease. By Arthur Latham, M.A., M.D., Oxon., M.A.Cantab. Author of the Prize Essay on the Erection of His Majesty's Sanatorium; Assistant Physician and Lecturer on Practical Medicine at St. George's Hospital; Assistant Physician at the Brompton Hospital for Consumption and Diseases of the Chest; Formerly Physician to Out-Patients, Victoria Hospital for Children, and Radcliffe Travelling Fellow in the University of Oxford. New York: William Wood & Co., 1903.

The perusal of the above volume has been a pleasure to the reviewer. Throughout the work there is abundant evidence of the author's grasp of his subject, of the well-balanced judgment which comes from practical experience, and of his deep interest in phthisiotherapy. The pathology is briefly considered, while diagnosis and treatment occupy most of the book. A strong plea is made for sanatorium treatment which, as a school of instruction and discipline, can never find a full substitute in the home treatment of the disease. The author, however, realizes that to many this ideal method is unobtainable, and to them he devotes a special chapter. The careful attention to details, so important in the treatment of chronic ailments, are here given very completely, while the underlying principles are at the same time brought out.

The writer has been a careful student of the subject and has compiled in the present volume the views published by him in previous articles, and in the essay which won the prize offered by King Edward for the best exposition on the subject of the erection of a sanatorium for the treatment of tuberculosis in England. The furnishing, ventilation, heating, lighting and arrangement of the sick room; the feeding, resting, exercising, drugging and daily program of the patient are all given clearly and completely at the same time, not too dogmatically, since the material for the text has been drawn from the methods in use at some fifty different sanatoria, some of which have been personally visited by the author.

The Care and Feeding of Children. By L. Emmett Holt, M.D. New York: D. Appleton & Co.

This book has the distinct merit of individuality of authorship and presents necessarily radical views on the subject. Its article on pasteurization of milk has been perforce abandoned by all thoughtful practitioners of large experience. The same may be said concerning the ultra views on artificial feeding, particularly when based on the use of a particular brand of laboratory milk. The statements regarding beef juice for young infants show that the author is hopelessly biased in favor of a theory rather than inclined to be convinced by opposing arguments of fact.

Clinical Treatises on the Pathology and Therapy of Disorders of Metabolism and Nutrition. By Prof. Carl von Noorden, Physician in Chief to the City Hospital, Frankfort, a.M. Authorized American Edition. Translated under the Direction of Boardman Reed, M.D., Professor of Diseases of the Gastrointestinal Tract, Hygiene and Climatology, Department of Medicine, Temple College; Physician to the Samaritan Hospital, Philadelphia. Part III. Membranous Catarrh of the Intestines (Colica Mucosa). By Prof. Dr. Carl von Noorden, with the collaboration of Dr. Carl Dapper. New York: E. B. Treat & Co., 1903. Pp. 64.

The American edition of von Noorden's and Dapper's short treatise on Colica Mucosa differs from the German one published by Hirschwald of Berlin, in this way, that in the original edition the names of the joint authors appear in the same type of print, while in the American edition Dapper's name is printed in so small a type that it is rendered almost obscure in comparison with that of his collaborator. Moreover, references 21 and 22 of the German edition alluding to Dapper's works have been omitted. What grudge does the American editor bear Dapper, the collaborator of von Noorden for many years?

The publication itself is a very meritorious one; special stress has been devoted to the chapter on treatment. The external appearance of the little book does credit to the publishers.

Diseases of the Stomach. A Textbook for Practitioners and Students. By Max Einhorn, M.D., Professor in Clinical Medicine at the New York Post-graduate Medical School and Hospital; Visiting Physician to the German Dispensary. Third Revised Edition. New York: William Wood & Company, 1903.

Unlike the second edition, this issue has been entirely revised and brought thoroughly up to date. The same practical character of the treatise is maintained, and the author has endeavored to leave the text unencumbered by exhaustive detail, thinking that for general use it would be less confusing and attain his end in making the work more instructive. It will be remembered that the first edition was the pioneer of American textbooks treating of the subject of stomach disorders, and the third edition shows the same stamp of the original worker. A profusion of illustrations, describing apparatus and microscopical sections, together with abundant diet lists, promise to make the present volume as popular as were its predecessors. As a work fitted for the general practitioner and the student, comprehensive yet concentrated, it can be sincerely recommended.

Cancers and Other Tumors of the Stomach. By Samuel Fenwick, M.D., F.R.C.P., and W. Soltan Fenwick, M.D., M.R.C.P. Philadelphia: P. Blakiston's Son & Co., 1903.

The present volume is divided into two parts, the first of which deals with gastric cancer, and the second with various other tumors affecting the stomach and duodenum. The book contains valuable statistics with regard to the symptomatology and frequency of cancer. According to the writers, a palpable tumor exists in four out of every five cases of carcinoma of the stomach. Carcinoma of the pylorus constitutes about 60 per cent. of all the cases. The initial symptoms of this group are usually those of indigestion, and for several months the chief complaint is flatulence and distension after meals, acidity, constipation, loss of appetite, and emaciation. According to the authors, cases of cancer of the stomach are occasionally encountered in which the symptoms are either entirely absent, or only appear at a late stage of the complaint (latent form). The book is full of personal experience of the two known clinicians. It will prove of great interest and benefit to the reader.

Therapeutics of Infancy and Childhood. By A. Jacobi, M.D., LL.D. Third edition. Philadelphia and London: J. B. Lippincott Co., 1903.

Five years have elapsed since the previous edition of this work has been published, and the author has endeavored to keep track of the times during the interval. Although the present volume contains no fundamental changes in substance and arrangement, it is a consistent exposé of the long experience of the author in the practice of a specialty with which he has been identified for half a century. In some respects his views on infant feeding are at variance with those of other pediatrists, but he maintains his side of the argument from the standpoint of large personal observation. He is still a firm believer in the efficacy of drugs for the cure of infant ailments, and prescribes them with great freedom. Altogether the work carries with it a distinct individuality that will commend itself to a large body of intelligent and conscientious readers.

The Changes in Peripheral Nerves Produced by Toxic Substances Applied to the Skin: A Medicolegal Study.—D. J. McCarthy gives the following résumé of his experimental work, undertaken because of the interest attached to a suit for damages instituted by a man suffering from a paralyzed condition of both arms, which, he asserted, was due to the action of chemicals on the exposed tissues. (1) An intense and extensive degeneration, the result of an acute inflammatory process, was produced by the local application of formalin to the skin, without destroying the continuity of or seriously interfering with the structure of the superficial tissues. (2) The action of hydrofluoric acid when locally applied does not differ essentially from other corrosive poisons. In weak solutions it may cause degenerative changes in the deep nerves, with minor necrotic lesions in the subcutaneous tissues without destroying the continuity of the integument. (3) The effect of carbolic acid in strong solutions is confined mainly to the superficial tissues, and it is only when these tissues are extensively involved (dry and hard, although there may be no blistering or ulceration), that the subcutaneous and deeper nerves become degenerated. (4) Acetate of lead produces irritative changes in the skin, somewhat similar but less intense than that produced by carbolic acid without involvement of the subcutaneous tissue or nerves. It would seem, therefore, that it is possible for certain poisons to penetrate the superficial tissues and cause inflammatory and degenerative changes in the deeper trunks without destructive lesions of the overlying tissues.—*University of Pennsylvania Medical Bulletin*, March, 1903.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending April 25, 1902.

	Cases.	Deaths.
Measles	283	7
Diphtheria and croup	335	45
Scarlet fever	296	24
Smallpox	..	..
Varicella	116	..
Tuberculosis	336	175
Typhoid fever	44	9
Cerebrospinal meningitis	.	..

On Taking Cod-liver Oil.—One of the best methods of prescribing cod-liver oil is to order it to be taken with an acid and a bitter. Ten or fifteen drops of dilute phosphoric acid in half an ounce of compound infusion of gentian forms a suitable vehicle. The oil should be poured over the surface of this at the time of administration. By commencing with a very small dose, and gradually increasing it, patients otherwise unable to take cod-liver oil, may in this way be educated to suffer, and in some cases even enjoy in large doses.—*London Polyclinic.*

Paratyphoid Fever.—L. F. Jermain says that the term paratyphoid fever has been employed in a clinical sense to designate infection with the paratyphoid or paracolon bacillus. Paratyphoid fever, however, does not constitute a clinical entity. In all, twenty-seven cases of undoubted typhoid fever with two deaths have been reported. The author reports three cases of this disease. All recovered. The average duration of the febrile stage was sixteen days. In each case three serum tests with typhoid bacilli were made at different stages of the disease, and in no instance could a positive reaction be obtained. Unfortunately no culture of paratyphoid bacillus was at hand to demonstrate a serum reaction in the first two cases, but in the third this was done, and a positive reaction obtained to Gwyn's paracolon bacillus. The author gives the details of the cases.—*The Wisconsin Medical Journal*, March, 1903.

Morphine Poisoning in an Infant One Month Old.—In the case narrated by J. D. Merrill one-sixth of a grain of morphine was given by mistake. The baby, which had been fretful from colic, soon became quiet. The mother, who was exhausted, fell asleep and did not waken for seven hours and a half, when she was roused by a queer noise from the child, who was found in convulsions. Strychnine 1-160 gr. was given hypodermically, artificial respiration commenced, and hot coffee injected per rectum. Nine hours after the morphine had been given there was complete unconsciousness, lightly contracted pupils, deep cyanosis, moist skin, respirations shallow and four to the minute, pulse weak, and reflexes absent. At intervals of three to four minutes there occurred general tetanic convulsions, beginning with a weak crowing inspiration, the chest becoming fixed, the whole body rigid, cyanosis extreme, and the pulse imperceptible. These spasms lasted from thirty to fifty seconds. As the family asserted this had been the behavior since first discovered, the convulsions were not ascribed to the strychnine. The bowels were flushed out; artificial respiration was kept up for eight hours. Hot baths followed by cold sprinkling, ice to the chest, rhythmic traction of the tongue, irritation of the epiglottis, dilatation of the anal sphincter and rectal injections of coffee were used in alternation over and over again. It was impossible to detect any improvement during the first four hours of work. About noon the respirations became a little deeper and increased to ten per minute and the color improved, although the spasms continued as frequently for two hours or more, gradually subsiding. After three in the afternoon, artificial respiration was necessary only at intervals. Breast milk was given by the spoon, and coffee and whiskey were injected at intervals per rectum, and the patient soon rallied.—*Chicago Clinic.*

Health Report.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, U. S. Marine Hospital Service, during the week ending April 25, 1903:

MEDICAL EDUCATION IN THE UNITED STATES.*

BY FRANK BILLINGS, M.S., M.D.,
CHICAGO.

ONE of the chief objects of the organization of the American Medical Association was the elevation of the standard of medical education in the United States. In the president's address, the Father of the Association, Dr. N. S. Davis, stated that "the purpose of the organization was the improvement of our system of medical education and the direct advancement of medical science and practice. †That medical education in that day was defective, as recognized by the founders of the association, is shown by the report of the Committee on Medical Education in the year 1850. The committee said, in part, as follows: "Medical education is defective because there are too many medical schools; the teachers are too few. There are too many students. The quantity of medicine taught is too limited; the quality too superficial, and the mode of bestowal of the honors of medicine too profuse and too unrestricted."

For many years the association showed its interest in and attempted to influence the elevation of the standard of medical education through a committee on medical education. The Transactions of the Association of the earlier years show many reports of this committee, which display much thought and effort on the part of the association to improve the status of medical education at that period of time. James R. Wood, as chairman of the committee, in the year 1858, recommended that the various medical colleges of America be requested to send delegates to a convention of medical colleges, to consider the matter of medical education. This movement finally resulted in the formation of the Association of American Medical Colleges, which thereafter represented, to a degree at least, the American Medical Association in its efforts to improve medical education. Later, the Southern Medical College Association was formed. Together these associations represent about 80 per cent. of the regular medical schools of the country, and these colleges have, in a general way at least, fulfilled the minimum requirements prescribed by the rules of the associations in regard to the preliminary education of students, the length of the college course, and the character of the curriculum.

About twenty-five years ago the Illinois State Board of Health, through the splendid efforts of Dr. J. H. Rauch, its secretary, made a report on the number and character of the medical schools of the country. This board adopted a minimum of requirements of medical schools as a necessary step toward the recognition of their diplomas by the State Board of Health of Illinois. This minimum requirement of the State Board of Health was gradually increased from time to time, with the result that many of the medical schools were obliged to raise the standard of medical education to enable their graduates to obtain licenses to practise in Illinois. Other States followed Illinois in requirements for better methods of medical education, with the result that the standard of education in the country was very much improved.

Medical Schools of the Country.—In the earlier days of our country, the need of physicians was met by the organization of medical schools which were, as a rule, proprietary in character. These schools attempted the education of physicians on the then existing conditions of medicine by teaching in a didactic way the principles and theories of medicine and surgery. The branches usually taught at that time consisted of anatomy, physiology, chemistry, materia medica, obstetrics, the practice of medicine and of surgery. But little opportunity was offered in the great majority of the schools for extensive, practical teaching in anatomy or chemistry, and but a moderate amount of clinical work in the co-called practical chairs. The course of medicine in the college consisted of two annual sessions of four or five months. The course was not graded. The student attended all the lectures and clinics taught during his first year, and the second year was a repetition of the first. This class of schools was rapidly increased in the course of time. The chief reasons therefor were the fact that it was recognized that a connection with a medical school was profitable, directly and indirectly. The prestige which the teacher enjoyed among the graduates and the laity brought him a remunerative consultation and private practice. In most of the States it was easy to incorporate and obtain a charter for a medical college. It cost comparatively little to conduct and maintain the institution. Lecture rooms were obtained at trifling cost. The dissecting room was not worthy of the name of a laboratory, and the chief expense in maintaining it was the cost of dissecting material, which was usually deficient in quantity and poor in quality. Medical schools were organized all over the country, without reference to the needs of the people. Medical education was prostituted. To obtain a sufficient number of students many institutions showed a most degraded disregard of the moral and mental qualifications of the matriculates. The income of the school was wholly derived from the tuition of students, and no applicant was turned away who had the cash with which to pay his way. To add to the facility of obtaining a medical college course, there were organized in some cities evening schools, the hours of college attendance occurring from 7 to 9 or 10 o'clock at night. These sundown institutions enabled the clerk, the street-car conductor, the janitor, and others employed during the day to obtain a medical degree.

In spite of the general tendency to increase the

*President's address, delivered at the fifty-fourth annual session of the American Medical Association, at New Orleans, May 5-8, 1903.

†Transactions of the American Medical Association, vol. xvi. 1865.

facility by which a medical degree could be obtained, there was a force at work to improve the methods of medical education. A few older medical colleges and an occasional new one set the standard high in relation to the existing status of medicine. There were earnest, forceful medical men in some of the schools who fought for a higher standard for matriculation and graduation.

The medical college associations exerted a splendid moral influence for good, and the State boards in all the more advanced States have, by mandatory legislation, compelled the colleges to raise the requirements in reference to the preliminary education, the length of the annual session, the time of medical college study, the character of the curriculum, etc. As a result, the status of medical college education has been very much improved in the last twenty, and chiefly in the last ten, years. But, improved as it is, there are evils which menace us, the chief of which still are too many medical schools, too many students, and inadequate facilities for the proper teaching of medicine.

The improvement in medical-college requirements has increased the cost of the maintenance of the medical college to a degree that it is no longer a profitable financial venture. There can be no dividends. Indeed, the proprietors of the private institution must often make up a deficiency in the annual budget. In spite of this fact, medical colleges have continued to increase steadily.

In 1877 there were sixty-five medical schools in the United States. In 1882 this number had increased to 89, and in 1901-2 to 156. The enrolment of students and the number of graduates have also increased, in spite of the fact that the requirements for matriculation and graduation have been increased. In 1882 there were* 14,934 matriculates, and this number was increased in 1901 to 26,417, and in 1902 to 27,501, an increase of about 100 per cent. in twenty years.

The number of graduates in 1882 was 4,115; in 1901, 5,444; in 1902, 5,002, an increase of about 25 per cent. in twenty years. If, in 1850, there were too many medical schools and too many students, what can we say of the condition to-day?

It has been estimated that there is an average of one physician to 600 of the population of the United States at the present time. The natural increase in the population of the country, and the deaths in the ranks of the profession, make room each year for about 3,000 physicians, based on the proportion of one physician to 600 of the population. With 5,000 or more graduates each year, a surplus of 2,000 physicians is thrown on the profession, overcrowding it, and steadily reducing the opportunities of those already in the profession to acquire a livelihood. The evil of an overcrowded profession is a sufficient cause of complaint, but the cause thereof is the important point for us to consider and, if possible, remove. To correct the evil, the ease and facility with which a medical degree may be secured in this country must be diminished. As before stated, there are now 156 medical schools in this country. Of these, 30 are sectarian, and 136 are so-called regular schools. Fifty-eight are medical departments of universities, of which 24 are State institutions. The relation of the medical school to the university in most instances is a nominal one only. In but few of them is the control of the faculty, or the finances of the medical department, vested in the university proper. In a very few of them the sciences fundamental to medicine are taught in the university. In the majority of these schools these departments are duplicated in the medical department, and are taught by members of the medical faculty. In most instances, too, the teachers of the fundamental branches are physicians who devote but a part of their time to teaching. They teach without salary, or for a nominal one only. Their remuneration is obtained by private practice, to which they must devote their best energies, to the detriment of their value as teachers. The clinical department of these schools is, in most instances, wholly inadequate. The majority of such schools depend on the general hospitals situated near them for the privilege of the use of clinical material Necessarily, these clinical advantages have great limitations, inasmuch as they can not be fully controlled for the purpose of proper bedside teaching, or for scientific investigation. Some of the medical schools which are connected with State universities are situated in small cities where it is impossible to command an adequate amount or variety of clinical material. The connection with a university, which many of the schools enjoy, is, therefore, almost valueless in a pedagogic sense. The majority do not differ materially from the private or proprietary schools in their value as teaching institutions. Ninety-eight of the medical schools in the country are private corporations, organized, maintained and, as a rule, owned by the faculty. If, in earlier years, these institutions were sources of direct financial profit to the owners, they have ceased to be so now—at least most of them. The evolution of medicine has made it necessary to extend the laboratory method of teaching. As these schools attempt to teach the whole curriculum, the erection, equipment, and maintenance of the necessary laboratories have so increased the cost of conducting the schools that they are usually no longer self-supporting. The temptation is, in such schools, to conduct them on a plane which shall just comply with the minimum requirements of the various State bodies, which regulate medical practice in the several States. They are maintained ostensibly to teach medicine, but in reality for the prestige which a professorship affords the teacher in his private and consultation practice. Proprietary schools depend on general hospitals and dispensaries for clinical material. What was said of the status of clinical teaching of the medical departments of the universities is true also of the proprietary college. These schools cannot hope to improve their present standards. The majority attempt to maintain laboratories and other expensive means of teaching which a modern medical education demands. But in how many of the laboratories worthy of the name? What kind and variety of instruments and apparatus do they afford? Are their teachers of the sciences of the fundamentals of medicine capable? They can not hope for better conditions, because the time when a student's tuition will pay the school for his instruction, if he is properly taught, will never return. Medical education of the future must be based on the status of medical science. That basis is recognized now, but is attempted in the great majority of our medical institutions in a very superficial way.

Scientific Medicine.—The great and important discoveries of Pasteur and the practical methods devised by Koch in bacteriology marked a new era in medicine. Before the facts made clear by these discoveries, the hypotheses and theories of other days have disappeared. Our knowledge of man and the lower animals and of the diseases and evils which afflict them has been revolutionized within the last twenty years. The advance in medical knowledge

**The Journal of the American Medical Association*, Vol. xxxix, No. 10, p. 574.

has been greater in that period than in all preceding time. Medicine now embraces many more subjects, chiefly fundamental ones, than were known twenty years ago. Formerly a very superficial knowledge of a few isolated facts in general chemistry and human physiology and a memorized knowledge of human anatomy and of materia medica enabled the student to learn the practice of the art of medicine and surgery. Now, the problems which confront the clinician and investigator in medicine and surgery compel him to have a good and working knowledge of general, physical, and physiological chemistry, of general biology, bacteriology, pathology, physiology, embryology, pharmacology, histology, and anatomy. The physician who has not a practical knowledge of these fundamental subjects can not clearly understand the methods of others engaged in scientific investigation, nor can he rationally utilize the discoveries of others in his work. Medicine to-day is applied science. If we utilize the knowledge of to-day in an attempt to cure and prevent disease, it must also be an experimental science. No one can practically apply or rationally experiment with what he does not know. The fundamental studies of medicine must, therefore, be acquired by all who desire successfully to apply them as sciences. The successful experimental application of these sciences has given us within ten years a knowledge of the method by which the invading bacteria affect the host, and has likewise developed a principal of wide application as a preventive and cure of certain diseases by the use of antitoxic sera. It has confirmed the principle of preventive inoculation, accidentally discovered by Jenner, and has enabled us to apply the principle in other diseases than smallpox. It has enabled us to know the methods of transmission of certain infectious diseases, and to know how to stamp out scourges like yellow fever, the plague, and malaria.

Through the evolution of Listerism, it has enabled the surgeon to evade every region of the animal body, and to save scores of lives formerly doomed to death. The freedom with which the surgeon may now operate has not only saved lives, but, indirectly, the knowledge of disease processes so studied during life has taught us many new facts in symptomatology, and has cleared away many fallacies concerning pathologic processes. It has given us many new methods of clinical study, and furnished data from the blood, the spinal fluid, the exudates, the sputa, the sweat, the fæces, and urine, which enable us to recognize disease much more readily than before.

Much as has been accomplished by experimental medicine in a comparatively brief period of time, there are vast fields to which the method has not been applied. With most of us, our present methods of clinical observation enable us to do little more than name the disease. In the vast majority of the infectious diseases we are helpless to apply a specific cure Drugs, with the exception of quinine in malaria, and mercury in syphilis, are valueless as cures. The prevention and cure of most of the infectious diseases is a problem which scientific medicine must solve. What is true of the infectious diseases is also true of the affliction of mankind due to chemical influences within the body. We know but little of diabetes, of the primary blood diseases, or of the various degenerative processes of age and disease. We hopefully look to chemistry to reveal to us the cause of these and other conditions. Experimental medicine must be the means of removing the ignorance which still embraces so many of the maladies which afflict mankind. Not every student, nor every physician, can become an experimenter in applied medicine. Nevertheless, every physician must be so educated that he may intelligently apply the knowledge furnished him by experimental medicine in the cure of such diseases as can be cured. He will no longer juggle with the life of his patient by an attempt to cure with drugs or otherwise, where no help is possible.

Methods of Medical Education.—The phenomenal evolution of medicine has multiplied the subjects of medical study. The character of these sciences requires that they shall be taught by the laboratory method. The laboratory method, too, has been adopted as the chief method of instruction in anatomy, pharmacology, and chemistry, formerly almost wholly taught in medical schools by didactic lectures. The laboratory method, while necessary to the proper and practical instruction of the student, involves an expense which is appalling when compared with the methods of teaching formerly practised in all schools, and still adhered to in many medical schools. The method is expensive, inasmuch as it involves more extensive buildings, much expensive apparatus and an increase of the teaching force. The instruction must be individual, or to small groups of laboratory workers, and this involves also an extension of the time of instruction. A physician engaged in private practice can not possess and retain the general and technical knowledge necessary to enable him to teach one of the fundamental sciences properly, nor can he devote an adequate amount of time to it. The teachers of these fundamentals must be investigators in the province of their respective sciences. They must give their whole time to the instruction of students and to original investigation. The thoroughness and accuracy of the training of the special senses; and in experimenting, which a student will receive from such teachers in properly equipped laboratories, will make him keen in intellect and sound in judgment. His desire for knowledge will be stimulated by the atmosphere of his surroundings, and will awaken in him a consciousness that through him and his work the knowledge of the world will be increased and humanity benefited thereby. But teachers of this character must be paid salaries quite as large as the remuneration of professors in the departments of arts, literature, and science. The salaries of such professors and of the corps of assistants which the laboratory method implies make the cost of the university or college far beyond the income which could be derived from the tuition of students. I believe it has been estimated that the laboratory method of instruction, now followed by all first-class institutions of learning, cost annually from $400 to $500 per student. But, great as the cost seems, it must be conceded that the present status of medicine demands the thorough instruction of students in these fundamental studies. It matters not whether his future may be that of a teacher or a practitioner of medicine. In either event he must apply his knowledge of the fundamental sciences to his work, and the result will depend on the thoroughness of his education.

Applied Medicine and Surgery.—To enable the student to utilize the knowledge of a thorough training in anatomy, physiology, chemistry, pharmacology, physiologic and physical chemistry, embryology, neurology, and pathology, he should be afforded facilities of equal rank in clinical medicine and surgery. To supply the student with proper clinical facilities involves several important features. Special hospitals, which would be absolutely under the control of the medical school, would be necessary. The hospital should be constructed with a

definite idea of teaching students and of making researches into the nature, causes, and treatment of disease, as well as to care for a definite number of patients. Hospitals for general medicine, surgery, and obstetrics would be essential. Such hospitals, with laboratories and equipped with instruments, apparatus, and library, would cost for their building and maintenance a very large sum of money. With such hospitals it would be necessary to choose the professors of medicine, of surgery and of obstetrics with competent assistants, of the same type as the teacher of the fundamental sciences. They should give their whole time to the work of teaching and to original research in the hospital. They should be men who have proved their scientific fitness for the important positions, by the contributions they have made to medical knowledge. They should rank with and receive the pay given to professors of important departments in arts, philosophy, and science. When so paid, they would be free to expend all their energy to teaching, and to experimental medicine—a career which would enable one to be of the greatest possible service to mankind. No life's work could be fuller or of greater self-satisfaction, and surely none would be more honorable. From these teachers and investigators the student would obtain instruction of the same systematic methods of accurate observation and investigation which were employed in the fundamental branches. He would receive thorough, conscientious drill in the fundamental methods of examination of patients, and his knowledge of the fundamental sciences would be constantly applied in this work. The trained clinical teachers would direct the student in thorough careful observation in the wards and at the operating table, would collect data to be submitted to experimental tests, and would conscientiously carry out the experiments in the laboratories of the hospital.

The brilliant discoveries which have made our knowledge of the cause and means of transmission of many of the infectious diseases have been chiefly due to the introduction of the experimental method of investigation. Teachers and investigators of the type mentioned will have the opportunity to make equally important discoveries in the broad field of the unknown in medicine. They will train students in the methods of research work, and constantly increase the number of investigators in the domain of medicine. And there is need for such men. We may give the great practitioners who have taught clinical medicine their due meed of credit for their excellent, painstaking, unselfish efforts as teachers. They have added to the sum total of our clinical data, have utilized the knowledge of the pathologist and the physiologist in diagnosis, and have tested and judged the worth of therapeutic aids in the treatment of disease. But as teachers they have not made students investigators or experimenters. Not one of the recent great discoveries in medicine has been made by such a man. He has used as clinical material hundreds of cases of pneumonia, rheumatic fever, tuberculosis, and chronic diseases by the score; his experience has taught him to recognize these diseases, even when the clinical manifestations are obscure, but he is no more successful than when he began to practise, in saving the life of the patient with pneumonia, in preventing endocarditis in rheumatism, in curing tuberculosis, or in checking the advance of a chronic hepatitis. It is time, therefore, that the clinical teacher should have the knowledge necessary to carry on experimental investigation, with hospital facilities for the work, that the profession may become purged of the shame of helplessness in curing so many of the common diseases of mankind.

The patients who will be received in these hospitals will be fortunate. They will receive the most painstaking examination and study, and the experiments made on animals in the laboratory will benefit the patients directly, inasmuch as more rational therapeutic measures will be applied in cases so investigated. In addition to the clinical teachers, who will devote all their time to teaching and research work in the special hospitals, there will be quite as much need for the clinical teacher, who is in private practice, in the general hospitals. Under his direction the student may himself investigate a hospital or ambulatory case, and undertake the care of the patient. His rich and varied experience in hospital and private practice will enable him to round out the student's college education. He will impart to the student a better idea of medicine as a whole. He will coördinate and arrange the isolated facts of clinical and laboratory investigation, and give them their true and relative value. He will teach the student the art of medicine; he will teach him that human sympathy and encouragement of the sick and dying are a part of his duty as a physician.

It would be most practical to make the clinical work of the third year a clinical drill and experimental course, given in the special hospitals, and assign the students of the fourth year to the general hospitals and to the clinical teachers who are in private practice. All the general hospitals and dispensaries controlled by the medical schools could be utilized in the fourth year for this purpose, and afford the student an abundance of clinical material and the benefit of the experience of many clinical teachers. Many of the assistants in the special hospitals, of the third-year course, would doubtless engage ultimately in private practice, and would, because of their scientific attainments, make excellent clinical teachers in the fourth year. A medical school conducted on the high plane advocated must necessarily be under the control of a university. Such a medical school would cost an enormous amount of money, and this can be commanded only by the trustees of a university of the highest order. That the money for the purpose of establishing and maintaining university medical schools with research hospitals and university extension clinical courses will be forthcoming can not be doubted. The world is awake to the great discoveries recently made in medicine. The wealthy men of this country have had their interest aroused as never before in reference to the possibilities and benefits which medical investigation will give to mankind. They now recognize that they and all posterity will be benefited by every new fact discovered in medicine, and that physicians thoroughly and scientifically trained are necessary to conserve the health of the people.

Three years ago Prof. W. W. Keen, in his address as President, deplored the fact that medical schools received relatively little aid in the form of endowments as compared with universities and colleges of philosophy, art, and theology. Since that time several millions of dollars have been given for medical education and scientific research. The signs of the times point to a brighter future of medicine in America.

Education Preliminary to Medical Study.—The subject of the educational requirements for matriculation in medical schools has been discussed at many meetings of this association in its earlier years, and later by the college associations, by the American Academy of Medicine and by the various State boards of health.

The requirements were at first lamentably low, and the efforts of the Committee on Education of the

American Medical Association and of the college associations had but little effect, because they possessed no legal power to control the schools.

The influence of the various boards of health of several States, notably Illinois, was more marked, inasmuch as these State boards possessed a mandatory power. The colleges were forced to adopt the minimum educational requirements of the State boards of health if their diplomas were to be recognized by the respective State boards.

These moral and legal influences to improve the preliminary requirements were almost nullified by the practice of a majority of the medical schools in admitting students whose educational status was examined into and judged by a committee of the college faculty.

This practice is still followed by a majority of the medical schools, and results in the admission of many students who are unable to fulfil the prescribed requirements. As a subterfuge, students are often matriculated conditioned in one or even several subjects. Then the student and the faculty committee forget all about the subject, and the student completes his course, goes into practice, and dies with the conditions still undischarged.

The present requirements of the college associations and of the various State medical examining boards and State boards of health amount, on the average, to a high-school education. The curricula and length of course of the high schools of the different States, and even in the same State, differ very substantially. However, if the medical schools now in existence would honestly require as a minimum education the diploma of a high school, without regard to the rank, it would be a marked advance over the present requirements as practised by most schools.

We must admit, too, that there are medical schools of such a low educational grade that they have no right to demand of their matriculates as much even as a common-school education. This fact that low-grade medical colleges exist is one of the most satisfactory explanations of the difficulty encountered in elevating the standard of preliminary requirements.

To get at the root of the matter the medical college must be brought up to the proper educational standard, and then, and then only, can be made a proper preliminary educational requirement.

University Medical College.—The present status of medical science requires and demands a university medical college course. By university medical college is meant a medical school which is directly connected with and a part of a university; the university fixing the requirements and controlling the admission of students to the medical department. The method of teaching both the fundamental and the clinical branches is on the principles outlined above. To properly prepare for such a course the student should have, as a minimum preparation, at least two years of study in a good college or university. The requirements to enter a good college or university would ensure a sufficient knowledge of the ordinary school branches and also Latin or Greek. During the two years' course in college his time would be well spent in the study of English, French, German, mathematics, history, philosophy, physics, chemistry, general and organic, and qualitative analysis, comparative anatomy and general biology. The amount of time to be devoted to each of these subjects would be the same as that of students of general science, as arranged in all college curricula, with the exception of a much more thorough course in chemistry, biology, physics, and comparative anatomy.

So prepared, the medical matriculate would be able to grasp all the intricacies of the subjects of the fundamental branches of medicine. With the addition of the full medical college course, as outlined above, his education would be equal in culture to that of the graduate in arts and philosophy. At the same time it would be practical and especially fit him for his work as a scientific investigator or practitioner, or for both.

With the medical profession so educated, a physician would be, in truth, a member of a learned profession. From an educational point of view, he would rank as an equal with the scholar in philosophy, law, and theology. As a man, he would be recognized as the greatest benefactor of mankind.

With the establishment of university medical schools, the first two years of work in the medical school will consist of courses in pure science. Then, doubtless, all universities will adopt the plan which two or three universities have already put in practice. That is, that the student who completes the first two years of the science course of a university, or at a college of good standing, may enter the sophomore year of the university and take the first two years' work in medicine, as the sophomore and senior years of the bachelor's course, when he would receive the degree of S.B. The student who completes the three years of the arts or philosophy course at a university, during which he should take a large amount of work in physics, chemistry, and biology, could then enter the medical college and after two years receive the degree of A.B. or Ph.B. After two years spent in the clinical school he would receive the degree of M.D.

This telescoping of the literary and medical courses affords the advantage of an economy of time, while it does not in any way lessen the value of the result to the student. In the one case the student secures the degrees of S.B. and M.D. after about six years of study, and in the other the degrees of A.B. or Ph.B., and the degree of M.D. at the end of seven years' study.

The Outlook of Medical Education in the United States.—Medical education must advance to its proper level if it complies with the present status of the medical sciences and the demands which continued evolution in medicine promises.

What does this imply? It means that the private —the prorietary medical school which is conducted for commercial reasons, must go. Acknowledge, as we must, the great value which the best of these schools have been to the profession and to the country, all such schools have lived past the time when they can be of value. The continuation of these institutions henceforth will be harmful. They can not command the money to build, equip, and maintain the laboratories and hospitals which a proper and adequate medical education demands. In the past their graduates have furnished the many great and influential medical and surgical clinicians of this country. In former days a graduate poorly prepared has been able, by indefatigable labor and post-graduate work, to place himself in the front rank as a clinical physician and surgeon.

To-day medical science demands primary instruction to fit a man as an investigator and scientific physician. If not properly educated he cannot grasp the great problems which medicine presents to-day as he did the more simple clinical facts which comprised the art of medicine and surgery a few years ago. In the future medicine must be taught in the large universities of the country and in the State universities which are situated in or near large cities, where an abundance of clinical material may be commanded.

The State university and the college which desires

to teach medicine, and is so situated that it cannot command clinical material, should confine itself to teaching the sciences fundamental to medicine. These should be taught as pure sciences, and should be included in the course for the degree of S.B. A college or State university ambitious to teach the medical sciences can do so without great cost. To attempt to teach applied medicine without proper and adequate hospitals, and with an insufficient number of patients would be irrational, nor can they command the necessary funds with which to do it. From such colleges and State universities the students could go to the larger institutions which are able to furnish the proper facilities for teaching applied medicine and surgery.

The general hospitals of many of the cities, now used by proprietary schools, could be utilized as clinical schools for both undergraduate and post-graduate teaching, conducted by the clinical teachers in the existing proprietary schools. Indeed, these hospitals could be utilized as university extension clinical courses. Necessarily they would have to be under the control and direction of a university medical school.

How many schools may be necessary to educate the number of doctors of medicine required annually in the United States? The question one can not answer, but it is safe to say that 2,500 graduates annually will fully supply the demand. This would imply about 10,000 to 12,000 matriculates. A minimum number of twenty-five and a maximum number of thirty-five medical schools should offer sufficient facilities to educate 10,000 students. The various State universities and the colleges which offer adequate science courses would educate a great number of students in the fundamental branches, or in the first two years of the medical course.

Medical Reciprocity between the States of the Union.—The low requirements of some medical colleges, and the want of uniformity in the requirements for a license to practise in the different States, has resulted in a condition which entails much hardship on a physician who desires to remove from one and to engage in practice in another State. The rules of most State boards of medical examination and of health are so stringent that a physician or surgeon of years of experience and of acknowledged skill and education, and the specialist who may be renowned in his field of work, are obliged, like the recent graduate, to take an examination in all of the branches of medicine and surgery in order to secure a license to practise in the State of his adoption.

To correct this evil, it has been suggested by a member of the American Medical Association, and concurred in by others, that a national board of medical examiners be organized; that the board hold examinations at different seasons of the year in the various large cities, and that the diploma so obtained shall be recognized as a license to practise in any one or all of the States and territories. The measure suggested seems to be practical and feasible.

In addition to this plan, it remains to be said that the degree granted by the future universtiy medical school will be undoubtedly recognized as an evidence of fitness to practise in any State in the Union. When we shall have a less number of schools and annual graduates the various States may safely and rationally become more liberal and discriminating in the conduct of their office.

The Influence of the American Medical Association.—The American Medical Association should maintain its interest in the elevation of the standard of medical education, one of the chief reasons of its organization. Its influence in former years was principally moral. This was of considerable value, for the reason chiefly of the high ideals of the founders and first members of the association, who advocated and fought for a high standard of medical education. In the future its influence should be manifold that of the past, for with the reorganization of the profession, the better methods of conducting its affairs, the increased and probably very large membership, and its great medical journal, should wield a great influence for good.

As the direct agent by which the American Medical Association may exert its influence in the elevation and control of medical education, the Committee on Medical Colleges and Medical Education should be made permanent and should be given adequate power and sufficient annual appropriation to make its work effective.

The American Medical Association should take as its ideal and standard of medical education the university medical college, with all the name implies in regard to the fundamental medical sciences, and to the clinical branches. It should use its influence to drive out of existence those proprietary medical schools, which are conducted solely as money-making institutions. These measures cannot be accomplished at once; but medical science demands it, the profession demand it, the people demand it, and look to the American Medical Association as the chief influence which shall accomplish this end.

SOCIAL CONDITIONS IN AMERICA IN THEIR RELATION TO MEDICAL PROGRESS AND DISEASE.*

By J. M. ANDERS, M.D., LL.D.,
PHILADELPHIA.

ANOTHER spacious year with its varied channels of energy and activity in medicine has closed. Whilst a faithful chronicle of the facts, data, and achievements showing the progress of internal medicine for that brief period would have proved an appropriate topic, I have availed myself of the choice privilege granted by this association of selecting my theme, and purpose to consider the subject of the relation of American social conditions to the progress of medicine and disease and the import of modern economic and professional tendencies in forecasting the immediate future.

The state of American society, founded on democratic ideals, is one in which the true function of the physician has ever been both intellectually and morally beneficent. It has ever been the fate of the medical profession, however, to have its past outgrown and stifled by the enthralling energy and life of its present and to forget to fix its gaze on what is grand and significant in inherited associations and opportunities. Conversely, the fundamental principle of human development, to wit, that the present is quickly passing under the control of the future, which transcends an enlightened self-interest in the present, is yet to be fully realized and appreciated. In the life of our civilization the physician has constantly found himself in the presence of golden opportunities to render a service to the community, to add his private thought to the public opinion. His high calling and the stage of social development from which he has proceeded have ever invited to the development of an expanding and humane spirit. He has been, however, in many cases too closely chained to his special work. Per contra, the individual member of commanding worth

*The oration in medicine before the American Medical Association, at meeting held in New Orleans, May 5-8, 1893.

and formidable individuality, like the Spartan and the Greek, has fortunately lent his own spirit to the genius of the great organism—the medical profession—and its higher destiny. That genius is no sluggard, and the motive of action is not the pursuit of gain or of personal aggrandizement, but an incessant advancement of our art and science and an application of the faculties to the higher interests of civilization. What is needed in medicine, from the standpoint of sociology at the present day in America, is the true "scientific spirit clothed with human interest," to give force and direction to the means available, not only with a view to the application of science to the healing art, but also to enable our profession to find its true place in the body politic and its intrinsic importance as a factor in modern civilization.

While there are certain things and events common to all in our psychic and social development, enlightened society will grant that the larger events in American history, assuming that "the first duty of society is the preservation of life and the comfort of its units, have not been so much dominated by legislative authority and social customs as by the march of science, more particularly medical and hygienic. In a country as vast as ours, however, there could be no uniform law covering the details of results in matters medical. These have been in the past and will in the future vary somewhat with the climate, physical conditions, degree of culture and opportunities presented by the widely separated regions. As a consequence, in displaying proportions and the practical results of scattered sections, the final adjustment of their claims only becomes perceptible and appreciable in their broader and higher generalization. The whole range of American historic data and events indicates an imperishable foundation of scientific achievement, and furthermore establishes firmly a relationship between medicine and the scientific principles underlying social conditions and phenomena that is both positive and vital. As touching the American medical history of the long past, we can see the major advances and their influence on social laws and the progress of civilization, only by grouping data and established facts and applying the process of generalization to these composite phenomena. In this connection it is to be regretted that our possession of unclassified facts is increasing with uncomfortable rapidity. A comparative and historic study of the medical literature of America, taking any of the older countries as a standard of comparison, in respect to this method of generalization, can scarcely prove even measurably satisfactory. Much of the history of native medicine is crude, and it is impossible to give it either crystallized or concrete form. Epoch-making discoveries and important, far-reaching scientific effort is justly the boast of the American profession. Systematic effort at a rigid classification of facts by the modern statistical method, however, has not been made, and only a partial scientific use of the ever-advancing events for the different historical periods has been attempted.

The concrete, comparative, and historic method of study which alone furnishes a proper basis for generalization and serves to point out the relations of medicine to other human activities, would insure a wholly fresh treatment of the earlier medical annals of America. The physician in his economic or professional dealings has not followed his self-interest in comparison with his measure of enlightment, to an equal extent with men in other lines of human activity, but the fruits of his unselfish labors are, when taken collectively, presented in the form of a heterogenous mass of details. It should be recollected that it is only the larger events, the accurately grouped facts after the method of generalization to which I have referred, that go to make up the bulk of medical history and medical aw. The practical results of the method of simple generalization would show clearly the final utility of medical and sanitary knowledge in the social universe a d manifest its relation to every-day life. Obviously in a young republic like ours something must be allowed to propinquity—to nearness to a confusing and disordered mass of facts and phenomena.

It has been well said: "A landscape is beautiful because distance has reduced its chaos of details into order."

Those endeavoring to make a personal study of the medical and sanitary requirements of our insular possessions, more especially under new and changed conditions, can not hope to gain more than a fragmentary knowledge. Much important and accurate information touching the social, climatic, and medical conditions and necessities, however, is available through the Division of Insular Affairs, in the War Department at Washington. It is clearly incumbent on the organized profession of the United States to undertake studies on a larger scale than that of individual effort. Moreover, the interrelations between tropical medicine and the sciences before alluded to, *i. e.* social and sanitary, is a question for the immediate future; thus step by step may we hope to erect a stairway that will lead to a new temple of knowledge.

The foundation for social order, education, and a fair measure of self-government under military rule having been laid both in Porto Rico and the Philippines, there is presented to the profession of the United States an opportunity amounting to an obligation to carry into those new possessions the light of modern sanitary and medical science. The peoples of those islands are as clearly entitled to the benefits offered by our science and art as they to those pertaining to their fundamental civil and personal rights, as guaranteed by the Constitution of the United States.

From the America that Cortez invaded until the present the most treasured resource of our nation to the physician has, in a peculiar sense, been human life, and in respect to this economic principle we are, at present writing, merely following in spirit our thoughtful forebears. The medical profession never has valued life in terms employed in denomination nor by its productive power, but rather measured it from a divine and humanitarian standpoint. Certain it is that with advancing civilization there has come a higher and higher appreciation of the value of agencies intended to promote longevity and minimize disease and suffering. And this tendency to preserve human existence, apart from sentimental considerations, is born of a principle long adhered to by the medical profession and continuously unfolding itself in the individual and in organized medical bodies. It is clear, without seeming extravagance of statement, that greater justice is done by the medical profession of America to the condition of society just pointed out than in foreign lands, since it is more thoughtful for the youth and hope of our profession. It is to the flower of that youth, with its new and hidden virtues, that we must look for disclosures in the province assigned to the higher and more complex professional bodies of the future. Modern democratic institutions, including medical schools, are in the ascending scale of civilization, infusing into our profession men who are armed with potent resources from the pedagogic world.

The present-day educational facilities and developments show an ever-increasing beneficent tendency,

and the standard of qualification has passed, or is passing, beyond the stage in which there is a mere desire to acquire an elemental knowledge of disease and its treatment in this country; a new character and a new vital and moral force is happily presuming to show itself in public action for the benefit of mankind. This genius stands ready to kindle its fires and materially aid in offering the means of human welfare and the revelation of new truths.

An appreciation of this fact by professional bodies is necessary in respect of the future; for medical societies organized to obtain the highest potency must compete successfully with other societies, or they will vanish from view in the stress of social and scientific evolution.

But though the obscure rival of the Goddess of Minerva, who had broken the loom of Arachne in her jealousy, executed wonderful tasks by her unaided strength, in the process of progress toward higher efficiency the individual ceases to be a factor of first importance. The process of development, whether considered in its economic, political, or purely professional relations, demands the subordination of the interests of the individual, to the larger interest of the organic whole. The dominant and controlling feature underlying an infinite variety and complexity of details of that upward movement of professional and social evolution is compatible with a remarkable simplicity of governing principle. Our plain duty is accordingly to endeavor to understand the nature of that governing principle which is distinctive and characteristic in that it does not regard the interest of existing members as supreme, but is seeking to establish conditions which are favorable to the interests of a larger future.

As regards the question of the relation of medical work and progress to our social system, the time is probably ripe for a revision of certain elemental and fundamental principles and customs, although it is obvious that neither social agencies nor the general public manifest a proper comprehension of its necessity. Whilst science is telling us about the pathologic intricacies of disease processes, their bacteriologic causation and cure with unparalled rapidity, important social and economic questions that affect especially the comfort and health of our teeming town-bred populations are subordinated. Again in a land of popular civil government the medical profession should be organized in a manner that would render it equal to enlarged duties which naturally should devolve on it. I refer to such matters as the control and regulation of asylums for the insane, municipal health boards, and the municipal hospitals for the sick poor, for contagious diseases and the like.

Certain tendencies of modern American life, considered with reference to the welfare both of the medical profession and general public, offer a most promising field for investigation and progress. The temptations of the practical, over-strenuous life of the present and past generations have left their impress on our profession. Something, however, must be ascribed to our nervous climate, reinforced by certain elements of the American spirit-aggressiveness and an unconcealed idealism. Neither should the power of the initiative of the American, his shrewdness and his energy be overlooked. It may be doubted, however, whether there have been accomplished achievements and results commensurate with the impetuosity that characterizes all paths of professional activity. The universal spirit of haste has taken possession of our professional life; it permeates the air of the age, and the principle cause of this state of affairs is to be found in our ardent, every-day ways of living, and its cure must result from a readjustment of the home life and habits of the professional and other classes. It means a return from our present-day restlessness and rush to a quieter period, to a "Mansfield Park," with its charm of quiet village life; a return to a normal life, with natural intellectual tastes, and to calm, patient, original observation that fosters vital force and successful endeavor.

If authors and investigators were to bring forward only definite and well-weighed pronouncements on all points at issue, it would carry us from the surface to the heart of things, and our labors would be more strongly marked by originality and power.

The spirit of undue haste which characterizes our national life is nowhere better exemplified than in American medical literature, despite its many virtues, its broad, liberal spirit and freshness. Never in American history, whether deliberately or unconsciously, has so much current literature been placed at the disposal of physicians. Too generally medical thought and opinion, which is not of necessity medical truth, finds literary expression. The obvious weakness of it all is an enforced tendency to waste one's time in reading matter which is unapproved by common opinion. Extending this thought, it may be questioned whether to carry views and ideas beyond the domain of existing knowledge does not hinder rather than facilitate progress.

There is a list of honor among American writers, and it embraces authors whose literary product shows not only a sharp scrutiny of facts, but also the highest and most characteristic utterances in medicine. Indeed, the worth and power of American medical literature, either in its content or method, scarcely receives an unprejudiced estimate abroad.

In the field of letters we point with inordinate pride to the late Dr. Oliver Wendell Holmes, and our contemporary, Dr. S. Weir Mitchell. Fiction by medical authors lives and will live in America.

It may be questioned whether American nationalism, as evidenced by the creation of a native literature, should be the principal aim, although the consistent use of American material is to be advised and encouraged. We need to retain the conservative European spirit and keep wide ajar the door that leads to the treasures of continental literary traditions. Foreign peoples are and have been immigrating by the hundreds of thousands yearly; they have penetrated into the remotest points of this country, carrying effective training with them in many instances. Hence, admitting that the prescience of genius is the possession of many, there are fewer distinctly American medical authors than at first blush would appear.

> "The Celt is in his heart and hand,
> The Gaul is in his brain and nerve;
> Where, cosmopolitanly planned,
> He guards the Redskin's dry reserve."

Acknowledgement is due the great value and significance of the unparalleled heritage handed down by the older nations, particularly England, Germany, and France. The path of fame for a nation no less than for an individual lies in the direction of constructive effort and sensitive receptiveness of the impressions and tendencies of the age irrespective of territorial limitations, and of a keen sympathy and close touch with the movements of the times in all lands.

Our literature is not an indigenous growth, yet stern of purpose; it is not, and, let us hope, never will be, sluggish in turning to foreign sources. It has, however, developed certain characteristic features, a distinct national flavor and a perfume "as plainly native as the arbutus."

American industry, with its attendant wealth and power, and the enlarged opportunities it offers to all classes of society for successful business enterprise, has quite generally proven attractive to and often filled with fervent hope the American physician, and with increasing means he has found his social position to improve.

In America the achievement of considerable financial success, however, is possible without taking high ground in a professional or ideal sense. The medical profession is integral in the effects of our economic evolution; it obtains stray glimpses of the avenue of glittering gold; but its central effort, if it desires to remain true to human perspective, contemplates a systematic development of its pecuniary, mental, moral, and social powers.

The tendency to gregariousness in American cities is in no specific direction more evident than in the medical profession; hence, success is and will continue to be an increasing difficult problem, a circumstance to be reckoned with, no matter what our meaning and ideals as a national profession. This portends in its last analysis the necessity of better training and equipment for every-day duties of the practitioner.

America stands in need of further reform in medical education and the immediate establishment of one authority—one licensing body; and self-created schools must place themselves in a position in which they can worthily assist in the execution of a scheme of higher national medical education. Professional ascendency in future will demand the creation of a homogenous and adequate standard of qualification for entrance into medical schools.

The relation of social conditions to disease is a topic that is becoming more and more insistent with the reflections that are the natural accompaniment of advancing knowledge.

A backward look reveals an embyro nation steeped in an arduous task, the subjugation of a continent, at the expense of unceasing physical toil. This necessitated an open-air existence, which resulted in a vigorous, hardy race. Then followed the integration of frontier villages, of larger and smaller towns, and life meanwhile became brighter and more piquant. For long generations the abandonment of rural life, the changed habits of living, the enforced pursuit of new and less healthful callings, too often from motives of personal comfort and even social expediency, and the universal tendency to overcrowding in town populations, resulted in a modification of the character and incidence of all leading diseases. It goes without saying that respecting the effects of our social conditions and climate on disease, the particular standpoint of our fathers was radically different from that of their children. Floyd M. Crandall has recently directed forcible attention to the fact "that never have such radical changes been witnessed in the habits of life and in human diseases as those in this country during the last half century."

Fortunately, agencies are at work looking to the socialization of the American agriculturalist and the amelioration of the ills due to overcrowding in large municipalities. This is a movement which, in the entirety of its scope, embraces numerous potent forces the federation of which promises to effect in time rural social regeneration. An organized effort has in several States been already initiated, and in the conferences held and in contemplation looking to the betterment of rural life, the coöperation of the medical profession is invited. Modern agencies, as improved highways, the introduction of the telephone, trolley lines, rural mail delivery, are socializers no less than economic facilities. In addition to these physical influences, marked improvement also comes from increased educational opportunities, farm organization, and the various functions of the church.

These socializing influences and forces tend to counteract the current of bygone days from the farm to the city; they likewise bid fair to become a factor of first importance in minimizing, if not actually counteracting, in due season, the ill effects of over-dense urban populations. It may, however, be remarked that the impoverished classes, especially the great immigrant contingent, will be far less likely to return to a rural environment than the well-to-do, and yet it will shortly affect the social and economic conditions as well as the vital statistics of the wage-earning classes. We may confidently expect a greater physical efficiency, a higher bodily standard, though municipal sanitation will be always required, and remain the principal factor in strengthening the powers of resistance to hostile environment. One point of common agreement is that, as a result of the rapid advances in sanitation and improved methods of treatment, there has been a notable decrease in prevalence and fatality of most infective diseases, particularly those more or less fostered by overcrowding (*e. g.* phthisis, diphtheria, diarrhœal diseases, etc.). Three well-defined classes, however, have, according to the census for the decade ending May 30, 1900, distinctly increased; they are cancer, affections of the kidneys, and the degenerations, fatty and fibroid. Thus during an increase in the population of 50 per cent. in the United States myocardial degenerations have increased 150 per cent. and certain types of chronic nephritis have also risen in frequency to nearly 200 per cent. The determination of the causes of this rapidly increasing frequency of these morbid states is clearly the task of the medical profession.

Respecting the degenerations—myocarditis, arteriosclerotic changes and kidney diseases—Crandall says: "The power of alcohol in the form of malt liquors to produce degenerate changes is so well-known to pathologists that the conclusion is irresistible that the radical increase in these diseases comes largely from changed drinking habits."

The notable increase in these morbid conditions, however, is not due to a single cause, and substantial progress can not result from too much emphasis on any one agency the undoubted potency of which remains undemonstrated.

It is probable that a more universal application of refined methods of diagnosis accounts, in a measure at least, for the apparent disparity in the number of cases of nephritis and myocardial degeneration in recent times as compared with the showing of older statistics.

The census between 1890 and 1900 indicates an increasing prevalence of two additional diseases, in respect to both of which progress in our knowledge has been slow and never encouraging. I refer to diabetes mellitus and lobar pneumonia. The census previously referred to indicates that chronic diabetes mellitus has nearly doubled in point of frequency in a single decade.

Whilst we shall continue to look to the bacteriologic laboratory for the discovery of the definitive cause of this metabolic ailment, and to the pathologist for a mind's-eye picture of the morbid state of the tissues, the data obtainable from an investigation of the manner and habits of life, which exert more or less etiologic influence, are of intrinsic medical importance, and would serve as accessory factors in diagnosis as well as straws for the application of measures for treatment.

Although impossible to recognize a boundary line between the "variables of health" and disease in

chronic diabetes mellitus, it can not be doubted that abnormalities of the glycolytic functions of the liver and pancreas, associated with inappreciable structural changes (more especially in the cells forming the islands of Langerhans) which interfere with proteid metabolism and the metabolic disturbances, are dependent in large measure on the overuse of the mind, intemperance, and irregular habits of body; in a word, on improper modes of living.

Physiology has contributed much to the intricate processes involved in the nutritional diseases. Morbid physiology (general pathology) is most intimately bound up with the modes and predilections of American life, particularly of the so-called privileged classes.

Diseases and conditions that are successfully treated by a correction of the mode of life are apt to be regarded as functional in nature, when, in reality, definite although undiscoverable structural lesions already exist, the foundation of an insidious and progressive disease already laid.

Now it is conceivable that a broader application of data as yielded by vital statistics would render more clearly recognizable the terrible significance of an enlightened public, living in idle acquiescence to positively injurious prevailing customs. A federation of forces, however, in connection with the investigation of special diseases even, is necessary to make this branch of inquiry productive of really important information; for example, the coöperation of committees on vital statistics with the creation of centers under the auspices of a national organization, such as the American Medical Association, would prove effective. I would instance lobar pneumonia, which, as before stated, is increasing in prevalence, as a disease in which the light of future investigation after this method of research would prove preliminary to important discoveries and decisions. Indeed, the local diversity in social conditions and climate in different sections which are far separated by geographical distances in this country, renders such a procedure an absolute necessity. The statistical data gathered by individuals, notable those of E. F. Wells, are of real value, and one point approximately settled is that the death rate by decades during eighty years is practically unaltered—"certainly not decreasing." The census for the decade between 1890 and 1900 shows an increased prevalence of this disease from 186 to 191 per 100,000.

A marked numerical increase in the number of cases of pneumonia has taken place since the advent of epidemic influenza[1], but this does not account for the slowly rising incidence of the disease during previous non-epidemic seasons. Other reasons have been given for the augmenting prevalence of pneumonia: increased facilities for travel and the tendency for people to congregate (Wells), the highly infectious character of the disease and the neglect of prophylactic measures in crowded centers (Walsh). Among accessory causes of the increased prevalence of pneumonia may be mentioned a change in the prevailing meteorologic conditions. As shown elsewhere, the wanton destruction of the native forests has been attended with an exaggeration in the range of variability of such meteorologic conditions as temperature and humidity. It has been long known and universally recognized that this disease bears a vital relation to the seasons, and that the greatest morbidity coincides with the most pronounced climatic changes. It is probable that the increased incidence of the disease will be shown to be dependent in part on augmenting prevalence of visceral degenerations, particularly of the cardiovascular system and the kidneys. Be it remembered that in a large measure these are the direct or indirect result of an era characterized by undue devotion to business, social excesses, and club life, with its attendant unseemly hours and unconcealed conviviality. It must be confessed that the extent to which lobar pneumonia is dependent on these degenerations acting as predisposing factors is imperfectly known, but it can not be doubted that a conservative attitude toward the question accords to them a prominent position among the agencies unfavorably affecting the prognosis.

Out of a total of 275 cases of necropsied lobar pneumonia at the Philadelphia Hospital for a period of six years from January 1, 1896, to March 1, 1903,[2] 250, or about 90.9 per cent., showed cardiovascular lesions, principally chronic endocarditis and general atheroma of the vessels. A small number of the cases, fourteen, or 5 per cent., showed acute plastic pericarditis, and eleven, or 4 per cent., chronic pericarditis. Renal lesions were recognized in 90.5 per cent. of the totality of cases. Chronic interstitial nephritis was noted in 145, or 52.7 per cent.; chronic parenchymatous nephritis in fifty, or 18 per cent., and acute nephritis in thirty-eight, or 13.8 per cent. Among the remaining twenty-five cases was one of renal calculus, another of renal tuberculosis, and in many of the remainder subacute nephritis was noted.

These figures afford strong presumptive evidence that renal and cardiovascular degeneration rank as potent predisposing conditions, and clear and convincing proof that they bear a close and vital relation to the high mortality rate of lobar pneumonia. It should be stated that the patients admitted into the Philadelphia Hospital belong to the pauper element of society and the subjects are principally adults.

TABLE I.

Ward.	Area in Acres.	Population for 1900.	Population per Acre.	Percentage of Deaths from Pneumonia.		
				1899	1900	1901
First	448.0	37,019	85.0	8.92	12.93	10.16

*Population and deaths occurring in Almshouse (Twenty-seventh Ward) do not appear in this table. Deaths in Almshouse, 1,637.

Forty-one (41) per cent. of deaths from pneumonia occurred after the age of forty years.

The reports of the health departments of leading cities, in particular that of New York, furnish valuable data from which important tentative influences

may be drawn, but sure ground can result only from research work of a broader character than has yet been undertaken in this country. From the record of vital statistics of Philadelphia and New York I have compiled two tables (*vide infra* tables No. 1 and 2), which show that pneumonia is more or less limited to centers, and these correspond in the main to the most densely populated areas, with their allied conditions of squalor and poverty.

Pneumonia, like other acute infections that prevail epidemically, shows a wave-like character, on comparing different years for the same locality. Exclusive of epidemic outbreaks, there is an evident tendency to a preponderating incidence in overcrowded districts, and among the impoverished classes. Thus the average mortality rate for four years in New York (*vide* Table 2), taking the eight wards which are most densely populated, from the tabular list is 18 per cent.

The fourth, sixth, seventh, tenth, eleventh, thirteenth, fourteenth, and seventeenth wards of New York City were embraced in this estimation. In contrast with the figures just given, eight wards, representing the most sparcely settled portions of the city of New York (*e. g.* first, fifth, eighth, ninth, fifteenth, sixteenth, eighteenth and nineteenth) gave for the same period of four years an average mortality of 14.3 per cent.[3] It was observed in the compilation of these mortality statistics that an elimination of the epidemic periods would make the differences in percentage dependent on the population somewhat greater.

TABLE II.

Ward.	Area in Acres.	Population U. S. Census of 1900.	Population per Acre.	Percentage of Deaths from Pneumonia.			
				1899	1900	1901	1902
First	154	9,516	62	11.2	1.81	0.9	12.1
Second	81	1,488	18	2.9	9.11	1.5	7.1
Third	95	1,797	19	10.3	9.61	2.9	10.5

Twenty-second	1,529	189,261	124	13.7	14.5	12.0	12.8
Average percent.	....	.....	.	13.0	16.0	12.8	14.4

In arranging the statistics for Philadelphia I have included only those wards in which the inhabitants were equally distributed throughout the entire ward. Per contra, wards having large area and a low population per acre, but this population located in certain sections of the ward only, have not been included. Thus the following wards became available for the purpose of contrasting those giving the highest with others showing the lowest mortality: First, Second, Third, Fourth, Fifth, sixth, seventh ninth, tenth, eleventh, twelfth, thirteenth, fourteenth, fifteenth, sixteenth, seventeenth, eighteenth nineteenth, twentieth, twenty-eighth, twenty-ninth thirtieth, thirty-first, thirty-second, and thirty-seventh.[4] The eighth ward was not included on account of being inhabited principally by a better-to-do class and on account of containing the Pennsylvania Hospital, the former condition lessening the liability of pneumonia, while the latter institution named would tend to increase the mortality from this disease, since many of its patients come from the third, fourth, fifth, and sixth wards.

The portion of the city west of the Schuylkill river was excluded from this computation for reasons similar to those just mentioned.

Out of the twenty-five wards included in our figures I have estimated a percentage of deaths from those showing the most dense population per acre allowing for the location of hospitals, homes, etc. (*e. g.* second, third, fourth, seventh, thirteenth, seventeenth, and nineteenth wards), and I find the percentage of deaths from pneumonia to be 12.8 per cent. Those wards showing less dense population tion, the first, ninth, tenth, sixteenth, twenty-eighth, and thirty-second, gave an average of 9.5 per cent.

The second, third, and fourth wards were occupied largely by foreigners (Italians, Russians) and showed the highest percentage of deaths from pneumonia while the seventh ward, which contains a large colored population, also shows a very high death rate.[5]

As shown by MacDougall's statistics, unfavorable occupational conditions probably have less effect in causing pneumonia than phthisis. In my own investigations it was observed that divisions of Philadelphia having an industrial population, modestly though comfortably housed, furnished a death rate but little in excess of that of the sections inhabited by the well-to-do. The whole subject of occupational diseases, eminently important to the medical world, is closely united with the social and economic conditions of the wage-earning classes, but its consideration here would lead me too far afield.

3. The writer desires to acknowledge with thanks the kind aid of Dr. William H. Guilfoy, registrar Department of Health, N. Y., in furnishing data for the above table.

4. The following wards have not been included in the estimation of the lowest percentages for the following reasons: The Twelfth Ward, while it shows a low population per acre (86) has a number of hospitals and homes which contribute largely toward it high death rate from pneumonia. The Second and Third Wards show a population of eighteen and nineteen per acre; there are but few children under five years and few aged persons living in these wards, and this lessens the mortality from pneumonia. The Twenty-first and Twenty-second wards, because they are occupied mostly by the well-to-do classes. The Fifteenth, while it has been included in my calculation, contains a large colored, Italian, and French population.

5. My acknowledgements are here due to Dr. L. Napoleon Boston for assistance rendered in connection with the statistics gathered in Philadelphia.

Traumatol.—Naudin speaks in terms of the highest praise of the use of traumatol in surgery. It is a therapeutic agent of the first rank, of the greatest value in surgery. It is indicated in those affections which have been treated so generally by iodoform. It has given excellent results as a dressing in all infected wounds and ulcers, especially ulcers of the legs of which the cicatrization is interminable; also in burns, in chronic suppurative otitis, and in ocular surgery. Personally, the writer has employed traumatol in venereal diseases (soft and indurated chancres, syphilitic sores, etc.) with surprising results. As a dressing for anthrax treated by the thermocautery, it has always dried up the secretion and brought about cicatrization far more rapidly than does iodoform, and the pain is almost nil. In several cases of suppurative rectitis, suppositories of traumatol, and especially insufflations of the powder, have caused the disappearance of the purulent secretion at the end of a few days, with consequent rapid cicatrization.—*La Médecine Modeine*, February 11, 1903.

CANCER AND IMMUNITY.*

By A. F. JONAS, M.D.,
OMAHA.

On such occasions as this we take great pleasure in recalling the past and dwell with great delight on the achievements along the lines that have most engaged our attention. We, as surgeons, especially those whose professional activity began in the pre-antiseptic period, review the successive changes from that period of expectancy to the present period of aseptic accuracy with the greatest satisfaction. No one can fully appreciate the present status of surgery who is not personally familiar with the period when wound complications were the rule and when faith was pinned on the belief in "laudable pus."

However great the change has been in surgical mortality, in the great improvement in wound repair and in the comparative freedom from wound complications at present, when we consider the number of diseases treated surgically, we must confess that many problems remain unsolved. We are not prepared to say, even now, as Boyer did in his great work, "Traite des Maladies Chirurgicales" (1814-1822), that he believed that surgery had reached perfection. The great advances of the past have taught us the imperfections of the present, and have pointed out to us the lines of research for the future.

At the outset, we are not unconscious of the fact that the profession itself is not yet agreed on many well-founded propositions. Many still cling with too much tenacity to old and deeply-rooted doctrines. Progress has been so rapid. The surgeon has, perhaps, been in advance of the physician along scientific and practical lines. The physician has observed that the surgeon has gradually invaded his field, thus creating some antagonism, but it has become less apparent, and more coöperation has been the rule since bedside observation and a clearer pathology have demonstrated the actual conditions.

In this connection, we are convinced that there is still too much difference of opinion between the physician and the surgeon regarding the so-called borderland cases. In that class of affections which primarily are so-called medical, and later may become surgical, in which the early stages are obscure, in which no positive diagnosis can be made, in which there is no improvement from the usual internal treatment, these constitute a class in which an exploratory incision would not only make a diagnosis clear, but would frequently lead to a cure.

Still, too much time is wasted in the medicinal treatment of such affections as goiter, tuberculous lymph nodes, pulmonary abscesses and gangrene, empyema, abscesses and tumors of the liver, obstruction of the biliary passages, diseases of the pancreas and tuberculous peritonitis. Chronic Bright's disease and ascites due to hepatic affections, always believed to be purely medical, have recently received the attention of surgeons, and the success has been sufficient to give much encouragement. The foregoing constitute a class of borderland cases in which it is often impossible to state where medical management ends and where surgical treatment begins.

Surgical advancement in the future will not consist so much in the radical changes in operative technic as in improvement in diagnosis and diagnostic aids. Many of our diagnostic formulæ are even now undergoing complete changes, and the future will lead us to a precision in the recognition of disease that we little dream of now. The early recognition of malignant disease is a problem of future development, especially malignancy affecting the internal organs. With our present aids it is impossible to recognize internal cancers sufficiently early to do a radical operation. Our only course at the present is an exploratory incision as soon as reasonable grounds for malignancy exist.

The field that seems full of promise and gives us hopes for great expectations in the future is that of immunity and immunization. It now seems that many tissue changes will be solved along these lines.

From our present viewpoint the question of immunity seems to tower above and overshadow all others. It involves the greatest problems for the future investigator to solve. Out of these researches will be evolved methods for the exact treatment of that great list of surgical affections which, at present, we can, fortunately, to a great measure, avoid by exact asepsis and can control, to a great extent, by antiseptic measures when once developed. But we still stand helpless in the presence of severe forms of septicæmia, pyæmia, tetanus, and other toxic invasions. Infections sometimes occur after the most carefully executed operative procedures. Accidental infections will always comprise a large proportion of our surgical material, a group of cases that furnishes a fatality all too great.

Our present helplessness in the presence of extreme toxæmia, we must confess, lies in our imperfect knowledge of the exact conditions under which the toxins operate. We may say, in a general way, that toxic bodies attack and destroy cellular elements. When, however, we study this question of infection in a more serious manner, we find that a flood of light has been thrown on this problem by Ehrlich and his followers.

The two greatest problems of the future, cancer and immunity, shall engage our attention to-day. Malignant disease seems to be on the increase. We stand so helpless in its presence when fully developed that we exert our feeble energies and grasp eagerly for any fact that seems to offer new light for its better understanding. It will be our effort at this time to, as briefly as possible, review the more important facts known regarding the etiology of cancer and then, after making clear to ourselves the revelations thus far made in the recent studies of immunity, determine, if possible, what relations, if any, exist between the two.

These considerations were prompted by personal observations made in a number of cases of undoubted malignancy that indicated the probable infectiousness of cancer. It is well known to us all that the infectiousness of most infectious diseases was first determined clinically, and that the clinical observations were later determined and confirmed microscopically and experimentally. The cases to be here related came under the author's personal care, and it is hoped that they may serve as contributory evidence to the observations already recorded by others *that malignant disease, under certain conditions, is infectious.*

Case I.—Mrs. H., aged forty years, of spare build, very small amount of adipose tissue, presented in the outer and upper quadrant of the left breast a hard, nodular, painful, movable, walnut-sized growth, of one year's duration. In the axilla could be felt a hazelnut-sized nodule. She had frequent lancinating, radiating pains in the breast. There were no evidences of acute or subacute inflammatory signs, no local redness or elevation of temperature. The clinic diagnosis of cancer of the breast was made and a radical operation was ad-

*Oration in surgery, delivered at the fifty-fourth annual meeting of the American Medical Association, held at New Orleans, May 5 to 8, 1903.

vised. Various family matters prevented her from submitting to an immediate operation, so that several months passed, after which it was observed that the neoplasm had diminished in size and it finally disappeared.

It may be urged that this may not have been a cancer or that no one should make a diagnosis unless there be a confirmation by the microscope. Is the microscope always certain? We have all observed cases that ran a clinical course of malignancy after the microscopic findings indicated benignancy, and vice versa. The pathologist always inquires after the clinical features. He is disinclined to give an opinion unless he can know something of the history and symptomatology. The above case, in every detail, resembled many others that were demonstrated microscopically to be malignant, consequently it would appear that we are justified in the clinical diagnosis of cancer.

Case 2.—Mrs. J., age thirty-five years, presented herself with an inoperable, extensively ulcerating carcinoma, involving the outer half of the right breast. The breast was unusually large. The outer portion of the ulcerating surface had been in constant contact with the upper and inner side of the arm. Portions from both breast and arm were removed for microscopic examination and proved to be alveolar carcinoma. No operation. She died in three months.

Case 3.—Mrs. D., age thirty-five years. She came under observation with a typical epithelioma of the cervix uteri. The vagina was large and relaxed, so that the neoplasm rested in contact with the lower portion of the posterior vaginal wall. Hysterectomy was recommended, but was refused. She presented herself again in two months, in which time there had developed an epithelioma at the point of contact between the cervical growth and the posterior vaginal wall. An operation was done, but the patient died from recurrence eight months later.

Case 4.—Mrs. G., age forty-five years. Came under observation with a typical cauliflower growth, involving the cervix uteri. Small particles were removed, which proved microscopically, to be carcinoma. The uterus was fixed, the growth appearing to be too extensive for operative interference. No operation was advised. After several months the neoplasm became smaller and gradually disappeared, the uterus becoming movable. At the present time, eight years later, she appears well.

Here we have four cases of undoubted cancer, each one of which presented some of the features of an infection, as in lupus or syphilis. Cancer is extremely slow in its development, its premalignant stage often lasting many years. This fact possibly may account for the negative outcome of inoculative experiments hitherto conducted. This long developmental stage is not unlike lupus, leprosy, and other forms of undoubted infection. In two of our cases we observed secondary growths which appeared at points where the primary neoplasm was brought, more or less continuously, in contact with previously healthy surfaces, a very common occurrence in nearly all forms of infection. In two of our cases the neoplasm disappeared spontaneously, the disappearance depending, no doubt, on some form of catabolism not yet understood. The elucidation of this form of cytomorphosis will give the key to the control, inhibition, and elimination of the atypical cell proliferation which constitutes malignancy.

The term cancer, so commonly employed, refers to growths made up chiefly of epithelial cells. There is really no good reason why the term cancer should be limited to epithelial growths. Cancer signifies "crab." It was originally used to signify malignancy and meant connective tissue growths as well as those of epithelial origin. For our purpose at this time we will limit the term cancer to epithelial neoplasms, and we will confine these considerations to its etiologic factors.

The mystery of its origin seems as deep almost as in the days when cellular pathology was unknown. No problem in pathology has received more thought and speculation. No subject has had bestowed on it more earnest effort and unremitting toil. Regarding its etiologic evidence, we must confess that we have only a mass of negative proof. When observers believed that they had found the specific organisms, scores of workers in the same field soon demonstrated their error. So to-day we can only say that the evidence which shows what we do *not* know of the cause of cancer is voluminous, and we must admit that we know little of its etiology.

We know something of its cell characteristics. We know that malignant disease is essentially a cell proliferation that has, biologically, many features that are opposed to the physiological tissues in which they take their origin. We find an atypical life history in the cancer cells. The nucleus divides in an asymmetrical way. We note that unusual karyokinetic figures in the nucleus are usual in new growths, pointing to changes in the cellular life history. Regarding carcinoma, certain bodies have been demonstrated, believed by some to be parasites, having some casual relation to the cell changes.

It is a well-established fact that the nucleus perpetuates the nature and function of the cell, and any change in the nucleus changes the cell in its function and process of division. According to W. V. Shaw, "the growth of cancer cells is then to be looked on as an effort of reproduction in damaged tissue, the incidence of the damage falling on the nuclear structures."[1]

This statement is based on observations made by him in connection with experiments on free swimming larvæ which developed from the stimulation of ova of certain lowly organized animals, causing a proliferation of cells. The ova had not been fertilized by spermatozoa. Adult organisms were not developed, but larvæ capable of independent life. These results were obtained by stimulating the ova with strychnia and by mechanical movements of the ova. This cell growth was compared to growth of tissue in partially damaged structures. Shaw believes that such damage alters the nature of these cell structures so that the vegetative functions of the cell run riot and the cells become parasitic toward the organism in which the growth is taking place. This view seems to find support in those connective tissue growths that develop in tissues that have sustained a trauma and in which the sarcoma develops; or in epithelial growths that form on surfaces that have been subject to prolonged irritation, as exemplified by the chimney-sweep's and paraffin-worker's cancer forming on an old chronic dermatitis; or a cancer forming on the site of a prolonged irritation by the smoker's pipestem on the lower lip. We have seen many times that cancer develops in epithelial tissue that has been subjected to irritation for a long time, usually extending over a period of years. We have long recognized irritation to be at least one of the causative factors. Just what metabolic disturbances take place and what the underlying causes are is not yet clear. That cancer is infectious has been proven by many clinical observations. This has been shown by Eberth, who collected twenty-two cases in which cancer was transmitted from lip to lip, tongue and palate. Behla reported eight

instances of death from malignant growths in physicians and surgeons who were inoculated from tumors, and four instances of apparent human infection from cancerous animals, dog and hen. He also alludes to a cancer epidemic among the white mice in the Pathological Institute at Freiburg as evidence of the contagiousness of cancer (Hektoen). Roswell Park believes that, for New York State at least cancer is increasing at an alarming rate.

Attempts have been made to show that cancer is endemic, peculiar to certain localities. Behla cites cases of Behrens, who found in a village ten deaths out of thirty-eight to be due to cancer. Pfeiffer, Powers, and Friesinger maintain that in certain houses (cancer houses) and marshy districts in the vicinity of ditches and streams containing sluggish water, especially if the stagnant and polluted water were used for watering garden vegetables and for drinking purposes, cancer is relatively frequent (Hektoen). This would point rather to a microphyte than to a microzoon as the etiologic factor.

Since infection of living tissue is believed in every instance to be due to bacterial invasion, naturally bacteriologists directed their attention toward the discovery of a specific germ. Very soon we had a long list to enumerate. Plimmer of London examined, in six years, 1,298 carcinomata, and in 1,130 he believed that he found parasitic bodies. Sjöbring laid much stress on cell inclusions. Russell described his fuchsin bodies, which were spherical or oval. L. Pfeiffer of Weimar published several monographs on the protozoa as a cause of cancer. Eisen brought out his Cancri amœbæ. Korotneff believed that he had found an organism which he termed Rhopalocephalus carcinomatosus. Bosr found and described an organism that he called Myxosporidia coccidia. Gaylord of Buffalo described at great length bodies that he believed bore an etiologic relation to cancer. Sanfelice of the University of Cagliara emphasized the etiologic importance of bodies that he named Saccharomyces neoformans. A very large number of other publications on this subject made their appearance, none of which differed in any essential point from those bodies just mentioned.

While the presence of the aforesaid bodies described by the different observers can be demonstrated and are present in a large proportion of the cases of cancer, all the requirements necessary to prove them to be the organisms solely responsible for cancer have not been fulfilled. The requirements necessary are (1) the organism must be isolated; (2) a cancer must be produced when the organism is introduced into another body; (3) the organism must be recovered from the cancer produced. It has been shown that, while the first requirement has only apparently been fulfilled, the second has been, in a number of cases, seemingly produced. More careful investigations have proven that the experimental growths were not cancer. The third requirement has not been fulfilled.

All of the work mentioned above was carefully reviewed in all its details by the cancer committee, who, in their second annual report to the surgical department of the Harvard Medical School, showed conclusively that the bodies described by the various investigators under different names were not cancer nor the cause of cancer. I can do no better than to quote in full the results of their labors. They bear the marks of painstaking and conscientious work. The conclusions of the Harvard cancer committee were written by Edward H. Nichols, and were as follows:

It has been claimed by the adherents of the theory of the parasitic origin of cancer that: (1) A proliferation of epithelial cells analogous to the lesions seen in cancerous tumors can be produced by certain well-known protozoa (nodules caused by the Coccidium oviforme). (2) Certain skin lesions characterized by epithelial cell proliferation are due to the action of a so-called protozoon (Molluscum contagiosum). (3) Blastomycetes are constantly present in human cancers and are the cause of the lesion. (4) By experimental inoculation of animals with blastomycetes, true epithelial or cancerous nodules can be produced. (5) Finally, the well-known endocellular bodies seen in the protoplasm of cancer cells have a definite morphology, are parasites and the cause of cancer.

It has been the object of the investigators, the results of whose work appear in the preceding pages, to study each of these questions. As a result of the lines of work pursued by them under the direction of the Cancer Commission during the past year, it is concluded that: (1) The lesion produced by the Coccidium oviforme is essentially a process of chronic inflammation, and is not analogous to the lesion seen in cancer. (2) The lesion of Molluscum contagiosum is characterized by certain changes in the epidermis, is not due to the action of a protozoon and is not analogous to cancer. (3) The so-called "blastomycetes" (saccharomycetes) of Sanfelic and Plimmer are torulæ. (4) The lesions produced by these "blastomycetes" (torulæ) are, essentially, nodules of peculiar granulation tissue, are not cancerous, nor, in any sense, true tumors. (5) Blastomycetes are not constantly present in human cancers. (6) The peculiar bodies seen in the protoplasm of a cancer cell are not parasites, nor the cause of the lesion, but probably are, in part at least, atypical stages of the process of secretion by glandular epithelium.

It is clear that in the present status of the etiology of cancer, bacteriologically considered, the case has not been proven. But it does not follow that it will not be shown that cancer is due to a specific and well-defined organism. It may be an organism so minute as not to have been brought within the range of the microscope. It is possible that no stains have yet been found that possess the requisite affinity for its complex molecular constitution. The necessary artificial medium for its cultivation remains for some future investigator to solve. Be it what it may, since the clinical features give strong evidence of the infectiousness of cancer, the search must and will be continued along the same lines.

In this search for a specific contagium, cellular metabolism must not be forgotton. Its consideration and study is perhaps more important than the isolation of a specific germ. It cannot be denied that the more exact our knowledge of cytomorphosis becomes the clearer will be our understanding of cell proliferation. It has long been understood that there must be certain stimuli that cause cell growth and certain inhibitors that limit cell development and exercise control in accordance with the requirements of the tissues. Certain other influences bring about a disturbance of the normal equilibrium between the stimuli and the inhibitors. It is evident that the exact nature of the stimuli, the inhibitors, and the disturbers must be ascertained. This involves a study of the cell constituents and the fluids that surround it. As we see, it is a question of chemistry.

In this connection it is important to take note of a very novel hypothesis bearing on the formation of new growths propounded by Homer Wakefield.

He believes that a neoplastic formation is not an exaggeration of anabolism, increased or excessive proliferation, but that it is a product of catabolic

stasis; that is, normal cell division is unimpaired, the anabolic process continuing to the point of maturity of the cell. It attains the meridian in its life and reaches the post-meridian state when it should undergo normal catabolism, a complete dissolution and disappearance of the cell. Instead, something has supervened to check catabolic changes, the cell becomes superannuated and its existence is prolonged until finally it undergoes various degenerative changes. Normal cell production continues, but normal cell dissolution is retarded or abolished, hence the cells accumulate, producing the appearance of what is regarded as cell proliferation.

This condition Wakefield has termed catabolic stasis or subcatabolism. He states that the intercellular substance is richly alkaline and that the tissue cells are more or less soluble in it. The cells, during the period of their growth, generate sarcolactic acid and during this period they are richest in protoplasm. After the meridian the cells offer decreased resistance to the solvent powers of the alkaline medium and lose their protoplasm, the nucleus alone remaining.

He infers that, before the meridian is reached, the acidity produced by normal cellular activity protects the cells by its neutralizing effects on the intercellular alkalies, and that this preserves the investment of protoplasm. Now, if from any cause, the normal alkalescence of the intercellular substance is reduced or if, in a given area, the acidity increases, catabolic stasis affects all the cells in that area. Suboxidation consequently takes place. It is therefore believed that cancer formation is an acid process.

Briefly, tumor formation, according to this hypothesis, rests on a stasis of catabolism, subcatabolism, and suboxidation, in the presence of normal anabolism. The cell inclusions, observed by many investigators and regarded by them as protozoa, cancer parasites and as blastomycetes, Wakefield regards as products of disturbed nuclear division. This new hypothesis, at present, rests only on theoretical grounds, but the arguments are so thoughtful and so suggestive that they deserve careful attention. Their chief importance, at this time, consists in the bearing out and support of the methods of research along chemical lines.

We are all familiar with Virchow and the birth of cellular pathology, with Ehrenburg and the growth of bacteriology, and now we have arrived at, and are in, the humoral or chemical era. The trend of all research at the present time is beyond cells and beyond bacteria. It is to determine the chemical operations in and around the cells. This line of research began in the leucocytes because they were the most available. In their study it was possible to establish basic principles. From the leucocytes to the erythrocytes was only a step and then the epithelial and connective tissue cells received attention. This field of research is a new one. It is occupied by a vast army of patient and earnest toilers. The fruits of their labors will be beyond our greatest expectations. It is our present purpose to see if the cancer problem can be solved along these lines.

What has malignant disease to do with immunity? The entire subject of immunity has to do with infection. It has to do with its nature, mode of action and control. Has cancer any characteristics that pertain to infection? Bacteriologically we have found none. Clinically we have a mass of evidence that would seem to place cancer among the infectious diseases.

In order to have a clear understanding of the modern conception of immunity it is necessary to review as briefly as possible and in barest outlines without comment the most important features of our present knowledge of the subject. Much material that may seem essential to a complete elucidation of this great and important subject, had to be eliminated on account of the limited scope of this dissertation.

More than a century ago we find that John Hunter was familiar with some antiseptic properties of the blood. He found that a small amount of putrefying material could be added to a given quantity of fresh blood without producing putrefaction. Consequently, he advanced his doctrine of "the living principle of the blood." This, as an observation, was almost forgotten, and its import was not fully realized until Nuttall, in 1888, began his systematic work in Flugge's laboratory, studying the antibacterial properties of the body fluids, especially the blood serum.

The greatest impetus to the study of immunity was given by Metschnikoff in calling attention to the participation of the leucocytes and other cells in the process of infection, establishing his well-known theory of phagocytosis. His views are so well understood that we need only to call attention to them at this time.

Following Nuttall, Pfeiffer discovered, in 1894, "the extracellular disintegration and solution of cholera spirilla in the peritoneal cavity of immunized guinea-pigs."

The greatest attention and interest was aroused by Behring's great discovery of antitoxic immunity. Bacteriologists at once endeavored to elucidate, by elaborate researches, the exact way in which immunity was established. Chief among these was Ehrlich. It was soon shown, however, that immunity in most bacterial infections did not depend, in the main, on the antitoxic principle.

Pfeiffer's phenomenon afforded a starting point, from which Metschnikoff, Bordet, Ehrlich, and Morgenroth began their labors and brought forth a series of discoveries that have been epoch-making.

A series of antibodies were differentiated and classified as antitoxins, antienzymes, cytotoxins agglutinins, precipitins, and coagulins. Antibodie, were in turn produced by these, with the exceptions of the antitoxins.

It was determined that to every cellular group of an animal species there appears to correspond a specific cytotoxin. These various toxins have been termed leucotoxin, neurotoxin, spermotoxin, nephrotoxin, thyrotoxin, etc.

These antibodies have been divided into two groups—first, the antitoxins which are single bodies; second, the cytolysins, whose antagonistic effects require the coöperation of two bodies.

Of these two bodies, the one which actually destroys the foreign cells is normally present in the cells or fluids or the organism, but it seems incapable of action without the intermediation of a body which is distinguished from it by a greater resistance to heat. The two elements composing cytolysins exist quite independently of each other, so that one may be present without the other or be artificially removed without affecting the other.

To demonstrate the mode of action and constitution of the specific antibodies, Ehrlich has propounded the theory of receptors or side-chains. The atomic grouping of the toxin molecule, which affects the union with antitoxin as well as with a particular cell, he has designated as haptophore groups.

In view of the fact that certain molecule groups of the living protoplasm favor the taking up of certain poisons, he has termed them receptors. According to his theory of antitoxic formation, after the introduction of toxins, the receptors are produced in ex-

cess, and finally are thrown off into the blood as useless ballast. The free circulating receptors are the antitoxins, termed amboceptors, intermediary bodies. The action of antitoxins is explained thus: They take charge of the hatophore groups of the toxin molecules and prevent them from approaching the receptors of the tissues[2]. There are as many receptors as there are toxins, while almost every day new ones are discovered.

Behring gives the most exact and brief definition of Ehrlich's antitoxin theory: "The same substance, which, when incorporated in the cells of the living body, is the pre-requisite and condition for an intoxication, becomes the means of cure when it exists in the circulating blood." Every antiserum protects only against substances through which it becomes immunized. Every antiamboceptor protects only against its particular amboceptor.

Ehrlich and Morgenroth found, in experiments with goat's blood, thirteen different new lysins, which represent so many receptors. "The receptors are in the cells, not for the purpose of linking poisons to the cells, but to seize certain foodstuffs, particularly proteids, and the toxins, bacterial and other foreign cellular substances, if capable of inducing the immunizing reaction, which chance to have the requisite combining affinities for the receptors."

The living body possesses bactericidal and cytolytic substances which may protect it by destruction of invaders or may injure it by destruction of its own cells, according to the mates with which they are paired.

In considering the physiological mechanism of the cells, we find that they are designed, primarily, for the assimilation of food, and, secondarily, to meet pathologic conditions, the production of antitoxins, cytolysins, and other similar bodies. The receptors are in the cells for the purpose of taking up foodstuffs, chiefly proteids. The toxins and bacterial cellular substances have combining affinities for the food receptors, if they are capable of inducing an immunizing reaction.

In producing immunization against bacteria, it is the intermediary body (amboceptor) which is generated. It has been found that these antibodies have a specific relation to the substances which caused their formation, as has been shown by the injection of a specific serum into an animal at certain intervals, of toxins, against which an antitoxin is desired.

The specific nature of these antibodies is further shown in their application to serum diagnosis, as shown by the Widal agglutination test for typhoid fever and the serum test in the diagnosis of bacillus dysenteriæ Shiga, an organism shown to be the cause of acute dysenteries by Flexner, Vedder, and Duval.

When Roux and Yersin discovered diphtheria antitoxin and Ehrlich the origin and mode of action of antitoxin, a lasting foundation for the study of immunity was laid. It was positively shown that "soluble toxins enter, as assimilable substances, into combination with constituents of the body cells for which they have an affinity," and are enabled to produce immunity or to exert toxic effects.

The expectations that we should soon be enabled to solve all questions regarding the action of toxins after the discovery of soluble, bacterial toxins, have only partly been realized, especially regarding the action of the pyogenic micrococci, which concerns us most as surgeons.

However fruitless, hitherto, the practical results regarding toxins of many pathogenic, and especially pyogenic, organisms, the principle has been established, and it is only a question of method and time when all body toxins and their antitoxins shall be definitely known.

Pfeiffer directed his attention to the bacteria and found substances, toxins, in cholera spirilla, which became free only after the bacteria were dead, and which were termed intracellular poisons. This was a most important step in advance, but we must acknowledge that we know as yet very little about the action and nature of intracellular bacterial poisons.

It is interesting to note from the result of Flexner's experiments with venom that their action on red blood-corpuscles, leucocytes, and nerve cells is like that of duplex cytotoxins, which depend on the combination of intermediary bodies contained in the venom on one hand, with corresponding complements in the cells or fluids acted on. This is shown by the addition of venoms to fresh blood, which brings about the quick destruction of the red blood-corpuscles. If the fresh blood has been washed with an isotonic salt-solution, so as to remove all the complement, we find that the corpuscles are not dissolved, but agglutinated. It seems that the venom serves chiefly to bring "into necessary relations with constituents of the body cells, poisons we already harbor or may generate, but which are harmless without the intervention of intermediary bodies."

Flexner and Noguchi have shown that the leucotoxic, the neurotoxic, and other cytotoxic properties of venom depend on combinations of venom, intermediary bodies with complements contained in the cells poisoned by venom, or in the fluids bathing these cells, indicating that the snake venom contains only a part of the complete poison.

Flexner and Noguchi also demonstrated that hemorrhages in various tissues of the body resulting from poisoning from certain venoms is due to the presence in venom of a cytotoxin which has the power to dissolve endothelial cells, which they termed endotheliolysin (hemorrhagin). It causes extravasation of blood through its direct solvent action on capillary endothelium.

The hæmolysins have been most extensively studied because of their great pathologic significance, and it has been found that many bacteria have hæmolytic power. The secondary anæmias, so constant in streptococcus infections, in pneumonia, typhoid fever, and other diseases, afford a most striking example.

Normal blood serum contains antihæmolysins which protect red blood cells from bacterial hæmolytic agents. Associated with hæmolysins are bacterial hemagglutinins, possessing the power to clump red corpuscles.[3]

Heuter and Klebs believed that thrombi were due to the coalescing of red blood-corpuscles. Welch calls attention to hyaline thrombi formed by agglutinated red corpuscles. White corpuscles are agglutinated by certain bacteria and also by pus cells.

What is urgently needed is a separation of these poisons and a determination of their source, constitution, mode of action, and degree of specificity.

It will not be out of place here to allude to the studies made of the ductless glands, because of their supposed bearing on immunity. Sajous urges that the adrenal extractives have a decided affinity for oxygen, offering a key to tissue respiration and to the functions of all other organs now classed as the ductless glands. It has been found that the red corpuscles are not the only carriers of oxygen, but that the blood plasma contains and distributes this gas. Schmiedeburg, Jacquet, Claud Bernard, and others demonstrated the existence of an oxidation

ferment in the plasma, and these bodies are now entertained as an oxygen-laden secretion. This secretion is believed to permeate nearly all the body elements. The blood also contains a fibrinogen body which combines in certain quantities with fixed portions of the plasma's oxygen. The changes in the temperature of the blood were traced to variations in the amount of the fibrinogen in the plasma. The adrenals have been shown to be connected with the anterior pituitary body by various sympathetic ganglia. The anterior pituitary body is regarded as the governing center of the adrenal system. Overactivity of this body increases the adrenal secretion, consequently oxidation, therefore vital resistance. Depression of the activity of the pituitary body causes decreased supply of oxygen, consequently depressed vital processes.

The thyroid secretion, thyreoidin, has been shown to sustain the efficiency of the pituitary body. Excessive thyreoidin production stimulates the pituitary body and produces exophthalmic goiter. Deficient thyreoidin production leads to myxœdema. The adrenals, the pituitary body, and the thyroid gland constitute the adrenal system. According to this line of research, it is believed that toxins act directly on the adrenal system, and, by decreasing or increasing its secretion, decrease or increase the oxidation process. Certain toxalbumins and many drugs stimulate the adrenal secretory powers to a certain limit, and, when exhibited in excessive doses, depress or arrest the functions of this system.

The posterior pituitary body has been shown by Berkley, Andriezen, and others to be the chief functional center of the nervous system. It is the center for such emotions as shock, excitement, etc.

It governs all organic functions through the nervous system. The secretions of the pancreas and spleen, according to Schiff, and later by Herzen, unite and change trypsinogen into trypsin, a solvent for the albuminous bodies in the pancreatic juice. This ferment performs an important part in immunizing processes, in that it destroys toxalbumins.

Viewing these labors in the light of Ehrlich's researches, the oxidizing substance represents the amboceptor; the spleno-pancreatic internal secretion, trypsin, represents his complement. To produce a proteolytic action of trypsin, fibrinogen and the oxidizing substances are required. These views are somewhat at variance with those commonly accepted, but are of sufficient importance to deserve consideration in this connection.

From the foregoing it would seem that the doctrine of phagocytosis plays an unimportant rôle. But we find that the French, or phagocytic school, at head of which is Metschnikoff, recognizes the full significance of acquired immunity and the cytolytic principles represented by the coöperative action of intermediary bodies and complements. The German, or humoral school, led by Ehrlich, recognizes the leucocytes to the fullest extent.

The chief difference between the French and the German schools consists in the belief by the advocates of phagocytosis, that the complements reside in the leucocytes, whereas the adherents of the humoral school believe that they exist in the blood plasma.

While, in what has here preceded, we have been concerned in the consideration of chemical problems, we must not overlook the fact that behind all is a governing force which resides in the central nervous system.

The practical outcome of these studies has been found in the production of antitoxic sera, some of which have been proven to have a definite and exact effect under certain conditions. We find these sera divided into two principle groups: (1) those that have an anti-bacterial action, and (2) those that have a purely antitoxic action. Of all the sera the diphtheritic is best known. According to Welch, the mortality of diphtheria has been reduced from 40 to 15 per cent. by its use.

Antitetanus serum has been disappointing. Reports coming to us from different sources are conflicting, the mortality ranging from 0 per cent. to 70 per cent. from practically the same methods, which consist in administering the serum by the subcutaneous, intracerebral and the spinal methods. Antityphoid serum has failed to fulfil expectations even more than antitetanus serum. The antistreptococcus serum of Marmorek, while it seems to have exerted a specific effect in purely streptococcic infections, appears to exert no influence in the presence of mixed infections. The antipneumococcic serum has not yet emerged from the experimental stage. Nothing can be said of its effects. The anti-plague sera of Haffkine and Yersin demonstrated that, as a preventive, it reduced the number of cases to one-twentieth and the mortality in a given number of cases was reduced from 33 per cent. to 13 per cent. (Calmette). The antitubercle serum has been shown to have a specific effect on tuberculous tissue, but remains powerless in the presence of mixed infections. The antivenom serum has been demonstrated to have a positive usefulness in certain snake bites. Calmette's antivenin has been proven to be of undoubted use in leprosy.[4]

Many other sera have been described, but their usefulness thus far has been shown to be of an uncertain nature. Consequently, we will leave them out of consideration at this time.

When we pass in review all that is positively known in relation to the question of immunity, we can not deny that some of the principles underlying this great question have, in a measure at least, been revealed. The evidence is conclusive that "the same substance which, when incorporated in the cells of the living body, is the pre-requisite and condition for an intoxication, becomes the means of cure when it exists in the circulating fluid."[5]

Ehrlich, in his investigations of diphtheria toxin, demonstrated "that soluble toxins enter as assimilable substances into direct combination with constituents of the body cells for which they have an affinity, and only thereby are enabled to bring about immunity or to exert toxic effects." Further, in connection with Metschnikoff, Bordet, Morgenroth, and Ehrlich, it is shown that "the organism possesses a power to produce substances specifically antagonistic to all sorts of foreign cells, cellular products, and derivatives. The substances capable of inducing this immunizing reaction appears to be mainly of an assimilable, albuminous nature, or at least intimately associated with such material."

The principle of toxins and antitoxins has become as firmly established as any other in medicine or surgery. We have noted that antitoxins from pure cultures have a certain affinity for and possess immunizing power in specific infections, but fail in the presence of mixed infections. We see at once that failure to immunize does not violate the principle, but that the method of application has been at fault. We know that diphtheria toxin has a specific effect for the products of the Klebs-Loeffler bacillus, and that it controls and cures in the presence of these, but fails when there is an admixture of other forms of infection. This is shown by the 15 per cent. mortality which still exists. We have noted that anti-streptococcus, tuberculous and plague sera have a specificand a decided effect in pure infections, but that they fail in the presence of other specific germs. We observe with satisfaction the

certainty of the action of a given antitoxin in its union with the toxin from which it was produced. It at once becomes apparent that, in the presence of several toxins or a mixed infection, it will require several antitoxic substances, a combination of antitoxic sera, or a serum containing different kinds of amboceptors, so combined as to meet and unite with the several toxins in a given case. Coley endeavored to meet such indications by combining streptococcus and bacillus prodigiosus sera in treating inoperable sarcoma.

These observations presage a revolution in therapeutics, which perforce means a refinement in diagnosis, beside which what we do now will scarcely bear comparison.

The inferences to be drawn from the foregoing indicate that the future work will be biochemic. It appears that the solution of cell metamorphosis, as it is observed in pathologic conditions, will be in the field of chemistry. Ehrlich's theory of the side-chains has given us a working hypothesis almost as practical as the atomic theory when applied to chemistry. It is not an idle dream to believe that the revelations of the future will not only consist in a complete exposition of cells and body fluids, or a perfect understanding of the governing brain centers, but may extend to the life principle itself, although life itself may and will ever belong to the unknowable.

Our chief interest, however, will always center in the cell and its governing influence. Just what influences are responsible for normal cell division may never be known. But it is within the bounds of human possibility to know what influences may be responsible for atypical and excessive cell growth. Excessive cell growth, both in the leucocytes and connective tissue cells in acute infections, we can assume to be due to toxins that are in excess of the amboceptors. The existence of cytolysins and anticytolysins is now undisputed. The one destroys, the other protects the cells. We have noted that the chief function of a receptor molecule is to combine with nutrient molecules, a metabolic, a chemical process. The birth and growth of the cell is restricted within certain limitations, and is regulated by chemical law. Now the problem depends on our ability to ascertain the exact influence that carries cell division beyond its normal bounds and causes excessive cell growth, as we observe it in malignant new growth. That the process is one of localized excessive nutrition is apparent. The localities of predilection are frequently at points where the cellular elements are exposed to frequent insults, where the tissues are damaged, establishing a *locus minoris resistentiæ*, as, for example, in the mouth gastrointestinal tract and the female reproductive organs. A point of least resistance, damaged tissue, if you please, always offer a soil for bacterial invasion. Cancer very often develops in tissues that have long been irritated, no doubt liberating a complement that unites with a specific infection when introduced under proper conditions. Such is not always the case, however. In fact, we know that in the majority of tissues that sustain irritations and almost constant traumatism for many years never become malignant. The simple traumatism does not develop cancer. A specific toxin must be introduced, probably also an intermediary body to complete the side-chain, which increases karyokinetic energy. We have noted in our studies of immunity that the life or death of the cell depends on its intra- and extra-cellular composition, so we may say that the whole process, whether it relates to normal or excessive cell growth, is chemical.

An objection may be urged at this point, which consists of the fact that the propositions of immunization thus far considered affect groups of cells extending over a wide range, *i. e.* the vascular, the muscular, and the glandular or cerebrospinal systems. It has been shown that cancer is always at the outset, and often throughout its entire course, absolutely a local disease. It would not seem rational to attempt immunization of the entire system against a strictly local disturbance. We will naturally turn our hope toward a method that will enable us to affect local immunization.

That local immunization is possible has been demonstrated by P. Römer in the following convincing abrin-immunization experiment: As is well known, abrin, which is the toxalbumin of the jequirity bean, will produce a severe conjunctivitis in animals and men. Ehrlich had demonstrated that rabbit's conjunctivæ became immune after the installation of abrin. Römer instilled into the right eye of the rabbit weak abrin solutions, the dosage being rapidly increased until immunization was produced. In three weeks the rabbit was filled. It was then shown that if the right conjunctivæ, which had undergone severe inflammation, were rubbed and macerated with a certain amount of abrin and injected into a healthy animal, it had no effect. But if the conjunctiva of the left eye, which had received no instillation, were rubbed and macerated with abrin and injected into an animal, death always followed. Römer concluded from this observation that in conjunctival immunizations a part of the autotoxin existed in the conjunctiva itself. A local antitoxin was produced.

It would seem that these results establish definitely the principle of local immunization in indifferent tissues. These observations have an important bearing on the adaptation of the cells in local affections. That local affections of various forms or general affections with local manifestions can be best managed by the local introduction of exceedingly small doses of the specific remedy, was shown by Professor Bouchard before a recent meeting of the Egyptian Congress. He found that articular rheumatism disappeared after the injection *in situ* of small doses of salicylic acid, and in some cases only half a grain. We must conclude that local cell metabolism can be influenced by local rather than by general diffusion. The inhibition of excessive cell growth must be accomplished in the same way.

It would seem then that the cancer question must be solved along the lines of chemistry. Since we know that contagious or infectious energy does not depend on the bacterium itself, but on its products, which are purely chemical, it would seem that it matters little whether the specific parasite is found or not. Since the cancer germ has thus far successfully eluded the most vigilant search, it becomes more and more evident that in the field of chemistry will be found the solution for our problem.

It will be difficult to rid ourselves of time-honored views. Purely theoretical speculation, like the hypothesis of cell proliferation from inclusions of embryonal matrices, according to Cohnheim, must give way to the demands of modern science that insist on actual observations and practical demonstrations.

Now then, will it be unreasonable to hope, that when protoplasmic changes are thoroughly understood and when the body sera have given up their secrets and the influences that govern cell growth, that we may also find the antibodies which will inhibit cell multiplication beyond natural bounds?

The studies in the field of immunity have, as yet, only assumed the proportions of the initiatory stage. A vast unexplored wilderness lies before

us. The pioneers have begun their work well. They have outfitted themselves in a manner that will, in the near future, enable them to throw unexpected light in the pathway of their conquest of discovery. They are only on the verge of this vast domain. What lies beyond the borders we can no more foretell than could Boyer know that in twenty-four years after his death we should have an anæsthesia, and that in fifty years the world would have an antiseptic surgery. And yet, in the light of our present knowledge, the hope, amounting to a conviction, arises in us that even in our lifetime, if we are spared a few years more, we will have an exact biodynamic and biochemic science that will make diagnosis accurate and precise, and one that will enable us to treat and control all infections with an exactness not now possible. While the surgeon is now constantly encroaching on the field of the internist, the time is not far distant when the physician may not only reclaim his own, but with it that large group of neoplasms known as malignant growths that from time immemorial has been the exclusive property of the surgeon.

Bacteriologic Study of the Blood in Thirty Cases of Clinical Typhoid Fever, Two of Which Proved to Be Paratyphoid and One Doubtful.—E. H. Ruediger says that among some of the general deductions from his and other recent work on the bacteriology of the blood in typhoid fever, the following are worthy of special stress: In all probability, typhoid bacilli circulate in the peripheral blood of all typhoid-fever patients during the first few days of fever, and at the beginning of relapses and recrudescences, disappearing from the blood shortly before the temperature starts to fall. As the typhoid bacilli are abundant in the peripheral blood during the first few days of the disease, it becomes possible by the demonstration of their presence to make an early and positive diagnosis, frequently before the reaction of agglutination can be obtained. By cultures from the blood, it also becomes possible to differentiate between typhoid and paratyphoid fever. The method of blood cultures is comparatively simple and easy, and can readily be applied to clinical work, both hospital and private. It gives the best means of making a positive diagnosis, provided it is applied early while the temperature is rising, and no examination can be considered exhaustive without such cultures.—*Medicine.*

Fistula of the Cornea.—James Moores Ball proposes the following operation to obviate the danger of injury to the lens during the treatment of corneal fistula. The keratome is to be introduced into the anterior chamber as in the first step in the operation for iridectomy. The tip of the instrument is to pass beyond the fistulous area, and the instrument is then to be held *in situ* while a cautery is used to destroy the epithelial lining, the tag of iris-tissue, which is often present in the fistula, and the bulging bleb of Descemet's membrane. The keratome is to be withdrawn carefully to avoid injury to the lens. Atropine and a compress bandage are to be used in the after-treatment. During the operation the lids should be separated by a speculum, and the eyeball should be fixed with forceps. It is neeessary that the forceps should be placed several mm. behind the point at whieh the keratome is to be introduced. If the forceps be placed on the globe at a point opposite the place at which the keratome is to be passed, the globe may be subjected to sufficient pressure to cause a rupture of the weakened area. The operation must then be postponed until such time as the anterior chamber shall have re-formed.—*St. Louis Medical Review.*

Ataxia without Tabes.—C. H. Cattle describes the case of a man who had an ataxic gait, and was unable to stand steadily with the feet together and the eyes closed. His knee jerk was lost, there were some patches of anæsthesia on the legs, but apparently no muscular wasting. It was not locomotor ataxia, beeause the pupils reacted to light and did not show any spinal myosis. It was a case of *alcoholic pseudo-tabes*, differing from the true tabes in the above-mentioned points, and in the fact that it was found that certain of the leg muscles did not respond to faradism, but did to a weak galvanic current, and this more readily with the positive pole on the muscles than with the negative (reaction of degeneration). The disease is peripheral neuritis, the pseudo-ataxy being caused by greater affection of the sensory fibers than of the motor. The patient rapidly improved after being taken into the hospital where he could not drink, and where galvanism and massage were applied.—*Medical Press and Circular.*

The Operative Treatment of Carcinoma of the Rectum.—F. M. Caird says that ten patients who were subjected to this radical cure of complete extirpation of the earcinoma, all recovered from the operation. In the males, the coccyx and portions of the sacrum had to be displaced or removed. In the female, at the most, only the coecyx was taken away. In four males and one female a sacral anus was established, over which the patient had fair eontrol, and in four females and one male the result was perfect, the patients being able to defecate normally after complete restoration of the anal eanal. In one instance only was primary union of the bowel obtained. The author describes the operation, two of the patients died within a year from local glandular recurrence, the others were alive and well, one four months, one ten months, three one year, one eighteen months, and one four and a half years respectively after operation.—*The Scottish Medical and Surgical Journal.*

ARTERIOSCLEROSIS.

THE *Albany Medical Annals* for March, 1903, contains a symposium on this subject. Dr. DeLancey Rochester says the causes are strains of occupation, and poisons introduced into, or generated within, the economy. Heredity may be of considerable importance, and almost all cases show two or more of these factors. The poisons introduced are syphilis and other infections, lead and alcohol. Those arising within the body are the products of faulty metabolism. The symptoms may be classed as cardio-vascular-hæmic, cerebral, renal, pulmonary, and gastrointestinal. Among the last, constipation and indigestion (intestinal and gastric) are important, and tympanites and eructations are not uncommon. Pulmonary symptoms are sometimes so pronounced that a clinical group of "spasmodic asthma and pulmonary affections" has been described; and chronic fibroid pneumonia is, in certain cases, the pulmonary expression of the disease. The renal symptoms are those of interstitial nephritis. Cerebral symptoms vary from mild dizziness and lack of memory (particularly recent) to violent vertigo, complete loss of memory, actual dementia, and apoplexy. Ocular symptoms are chiefly loss of vision. The diagnosis ultimately depends on the vascular symptoms; cardiac hypertrophy, pulse of long duration and high tension, with an increased second sound over the aortic orifice. The appearance and persistence of vague pains, or paræsthesiæ (tingling, prickling, numbness or persistent coldness), or sharp neuralgic attacks, demands a search for the vascular changes. Arteriosclerotic malnutrition is either flabby and corpulent; or sallow, emaciated, and rather cachectic with arcus senilis. More or less anæmia is always present, and weakness, shortness of breath on exertion, præcordial distress, vertigo, and nausea may occur. Dr. G. R. Butler says that when the coronaries are not involved, the main, and for a time, the only, symptom may be hypertrophy of the left ventricle, chiefly in middle aged or quite young, robust, muscular men, mostly the victims of some intoxication, or large eaters, or the subjects of hard and prolonged muscular work. Subsequently dilatation and ruptured compensation occur. When the coronaries are involved, fibroid degeneration of the heart, angina pectoris, coronary thrombosis with sudden death, and, rarely, aneurysm or rupture of the heart occur. Of these sequelæ chronic myocarditis is by far the most common. The earliest symptoms which, when present, arouse a justifiable suspicion of it, are a sallow, pallid face, with enlarged venous radicles, premature grayness, a tendency to a wet and leaky skin, and a distinct loss of strength and energy. Compared with the strength of the apex beat, the pulse is apt to be weak, and is irregular or intermittent. Frequent gastralgic attacks are to be regarded askant. They have extreme importance, and later become typically anginal, with irregular, weak, often slow pulse (50-30). These latter are rather characteristic. In advanced cases the physical signs of dilated heart with a gallop rhythm, often also the systolic apex murmur occur. True angina pectoris is a rather rare symptom. If angina occur, even in the absence of hypertrophy and of palpable arterial hardening, along with heightened tension and accentuation of the aortic second sound with a peculiar, slightly harsh or clicking quality at the instant of closure, it is safe to say that the angina is genuine and not false. Several instances of the Stokes-Adams syndrome were observed; a permanently slow pulse (20-40), with peculiar, vertiginous, syncopal, apoplectiform or epileptiform attacks, usually in elderly, far advanced arteriosclerotics. Dr. I. P. Lyon discusses the renal condition, which may be the primary affection, or secondary to arterial sclerosis. The discrimination between the alternatives depending in any given case upon the history, the degree of arteriosclerosis compared with the amount of renal impairment, the sex, the age, and the course under prolonged observation. Syphilis, alcoholism, plumbism, gout, and long-sustained, severe physical strain point strongly to probable primary arterial disease. In the latter, also, the patient is likely young or middle-aged, owing to causal syphilis or alcoholism. The practical value in the discrimination lie in the avoidance of adding to the strain of the stiffened arteries by kidney flushings, sweat baths, and similar drastic measures, and in the avoidance of mistaking the pulse of small volume for one of low tension and consequent prescription of digitalis. Dr. C. G. Stockton discusses the effects upon the digestive system, which include thrombotic gangrene of the intestine and also of the stomach. He cites cases in which meteorism, colic, and other disturbances are due to deficient blood supply, and improve under the nitrites. His record book shows that about 60 per cent. of arteriosclerotics complained of digestive symptoms. Dr. William Browning says Demange has reported scleroses in the cord, not of insular form, as definitely of arteriosclerotic origin. Clinically, a picture not unlike lateral sclerosis is produced. Therapeutically, these cases improve most under the vasodilators. In the brain we have the organic paralytic forms, the outcome of a progressive, or severe arteriosclerosis, which often presents a syphilitic or traumatic etiology. Also we have the ordinary and best known type, of which the following signs are regarded as suggestive: vertigo; various paræsthesiæ and pareses; transient aphasias; ataxic movements; faint turns; hebetude and sleepiness; pains or pressure in the head; impairment of memory; excitement or mental confusion; lack of energy; obstinacy, a tendency to depression, fear of losing the mind, intolerance of mental strain, alcohol and tobacco; and occasionally convulsive phenomena, not rarely

Jacksonian in type. Flickering before the eyes or transient blurring of vision and contraction of the visual field occur in advanced cases. Of great diagnostic importance is the tortuosity of the smaller retinal vessels and of their terminal twigs. Much of the "neurasthenia" of middle age is of arteriosclerotic origin, and the same is true of the traumatic psychoses. The author doubts the bad omenship of arcus senilis, and considers that tortuous temporals and hardened radials have but a limited bearing. The treatment should include open air life, mental and physical relaxation, laxatives (particularly salines and sulphur waters), regulation of diet, proper sleep and anti-lithics, including iodide. Dr. Adolph Meyer says at present we can distinguish no distinct arteriosclerotic form of insanity. His autopsies are classified into: cases with focal lesions involving varying degrees of dementia, cases with foci of softening without focal symptoms, cases with multiple very small foci of softening, especially the cortex, in several of which epileptic attacks developed, and cases in which the lesion is fairly uniform and diffuse.

THE USE OF SALICYLIC ACID AS A FOOD PRESERVATIVE.

THERE has been going on for a number of years an agitation upon the question as to the danger from the use of various antiseptics for the preservation of articles of food, and there have been many and warm arguments for and against such practice. The question is one of those upon which it is difficult to render an absolute opinion of general application, but concerning which a decision can be reached only after a careful consideration of all the facts in the individual case. The factors that enter into such a decision are the toxic activity of the preservative used and the amounts in which the food thus treated is taken, together with the harm that may result from failure to employ the preservative. Some aspects of this important question are discussed from a practical point of view by Drs. C. J. Macalester and T. R. Bradshaw (*Lancet*, March 14, 1903, p. 717) in the course of a paper read a short time ago before the Liverpool Medical Institution. They deal more especially with salicylic acid, which, it has been contended, is injurious to health because (1) it is an antiseptic and antifermentative and therefore likely to interfere with the digestive processes by destroying the digestive ferments; (2) after absorption it is likely to affect adversely the general health and to interfere with nutrition; and (3) it is an irritant and therefore likely to damage the mucous membrane of the gastrointestinal tract. It was, however, found, on actual observation, that the digestive processes proceed in the presence of salicylic acid in practically saturated solution, namely one to 500, and that this exerted no greater retarding effect than many articles, such as table salt, that are always present in a mixed diet. As a matter of fact, salicylic acid is rarely if ever used as a preservative in such large proportions as this, as the resulting taste would prevent the popularity undiluted of any substance containing it. Further it was found by actual test that as much as five grains of the acid could be taken daily by an adult and proportionate amounts by children without doing harm or causing ill health. This is a larger amount than would be taken with preserved food by any individual under ordinary conditions, but even when given in larger amounts, as in the treatment of acute rheumatism, and for considerable periods of time, it is not known to have produced toxic or other ill effects, such as damage to the gastrointestinal mucosa. A further justification for the employment of salicylic acid as a food-preservative is the fact urged by these writers that it renders possible the use, by the poorer classes of the community, of preserved fruit, fruit juices, and the like at moderate cost, so that the practice has a distinct economic value. Salicylic acid may, in this connection, take the place of alcohol with its attendant physiologic dangers.

From the foregoing observations, in conjunction with other evidence, we are asked to believe that the use of salicylic acid as a food-preservative not only is free from deleterious effects, but it further permits of the manufacture and employment of wholesome, agreeable, and inexpensive articles of food without intoxicating properties.

Against this plea it must be admitted that good wholesome food, as food cannot be improved in any shape by the use of preservatives. We may congratulate ourselves, perhaps, that under certain conditions these agents may not do positive harm, still they by no means add to the value of food as such. The argument that they place otherwise inaccessible and expensive articles within easy reach of the poor is hardly forcible enough to offset the danger of favoring adulteration in general, and giving unprincipled manufacturers the freest possible opportunities for the fraudulent practices to which they are so notoriously addicted.

MR. HUTCHINSON ON LEPROSY.

In a recent issue of the *Hospital* there is a calm and well-balanced review of the recent investigations of Mr. Jonathan Hutchinson on the leprosy question. It is well known that he has advanced the view that the great cause of the disease is the consumption of decayed or badly cured fish. It is certainly remarkable that at an age when most men of his ability and standing seek a well-earned repose, that he should undertake long and fatiguing journeys solely in the pursuit of science and in seeking an elucidation of one of the vexed questions of medicine.

The theory of contagion in the disease is still unsettled. The former unreasoning and cruel dread of the malady has long since abated, and as the *Hospital* remarks, "the general experience of modern times has led most communities to realize that the fear was very much in excess of the danger." There are always a few lepers in England but the nature of their malady is hardly recognized except by the physicians who have them in charge, and there is no authenticated instance of the disease being conveyed to the families of the sufferers. But during his inquiries in Africa Mr. Hutchinson arrived at the conclusion that such spreading is liable to occur amongst the members of uncleanly communities, and that it is brought about, in his belief exclusively, by the contamination, by leprous hands, of the food that is eaten by other members of the family of which the leper forms part. This, which he describes as "commensal communication," he regards as practically the only way in which the disease is liable to be conveyed from one person to another, or to occur independently of the consumption of

the badly cured fish, which he regards as the natural home of the leprous bacillus. It follows that he also regards the buccal or intestinal mucous membranes as the only channels through which this bacillus can find entrance into the human subject.

Mr. Hutchinson visited the leper institutions in India in order to determine the validity of the argument against his theory—namely, that the natives there assembled were not fish-eaters. He found that this contention was not true. He learned that fish was largely eaten, and that it was among the fish consumers that this disease was most prevalent. The most striking instance of this fact was noted among the "Salsette Christians," so called. These people are the descendants of the converts to Romanism made by the Jesuits under Portuguese rule. They number about fifty thousand, and yet among this number there were found in one asylum 369 lepers in contrast to 324 cases furnished by the whole of the enormous Mussulman population of the Bombay presidency.

Questions like the one considered are never settled except by the collation of facts from wide areas of territory and by different observers, and when the entire truth becomes known, the sweeping conclusions of the pioneers generally require modification in view of the later experience of the settlers. But there can be no doubt that the observations of the distinguished physician and traveler have greatly increased the date at our command for an intelligent solution of the vexed problem. His motives are most praiseworthy. As the *Hospital* well observes, he belongs "to that order of philosophers who love truth better than their own system."

Official Supervision of Antitoxin and Virus Production.

Under the provisions of an act of the last Congress, the Secretary of the Treasury has issued regulations governing the preparation, propagation, and sale of virus, serum, toxin, antitoxin, and analogous product in the District of Columbia. As the act provides that no interstate commerce, and no importation or exportation shall take place in such articles, unless in method of preparation they shall conform to that required for the District of Columbia, these restrictions amount to a far-reaching system of supervision. The chief requirements are that the place of manufacture must be licensed, after inspection by an officer of the Public Health and Marine Hospital Service above the grade of assistant surgeon, and upon his recommendation; and that the license shall be good only for one year, it being, of course, renewable on expiration. The license is liable to suspension or revocation by the Secretary of the Treasury, upon the recommendation of an inspector. Inspectors are to make unannounced visits, and shall examine into the methods in use, and shall, from time to time, purchase specimens of the products in the open market for examination and test as to efficiency. All specimens are required to be labeled with the name of the product, the name, address, and license number of the manufacturer, and the date beyond which the contents cannot reasonably be expected to yield their specific results. Fraudulent labeling, or other violation of the provisions of the act is punishable by fine of not exceeding five hundred dollars, with or without one year's imprisonment. These regulations go into effect August 21 next. As an official guarantee that the label shall stand for a definite degree of potency, and assured standard of reliability, this is a step in the right direction.

The Army Medical School.

On April 14 thirty-eight assistant surgeons in the army received diplomas in military surgery, sanitation, and other special branches, and were pronounced qualified to act as army surgeons in the field. The Army Medical School of this country, established in 1893, has since its inception, considering the inadequate facilities for thorough instruction provided by the government, done exceedingly well. Included in its faculty are some of the most brilliant surgeons, pathologists, bacteriologists, and sanitary experts in the United States. The successful result of the investigations undertaken in Cuba to solve the yellow-fever problem, will ever be remembered to the honor of the Army medical corps. The work already performed in the Philippine Islands by members of the Army Medical Service has been most satisfactory, and it may be predicted that American investigators in the Far East will play an important part in tracing the origin of many tropical diseases through the instrumentality of the same service. The means at hand for training the young medical men of the army have been up to the present woefully defective. The hospital facilities are especially meager. The only general hospital available for the instruction of the student medical officers is the old general hospital at the Washington barracks, which is lacking in almost all the essentials of a modern hospital. This condition of things, however, will soon be at an end, for steps will soon be taken to erect a new general hospital in Washington, which will be in every detail all that an up-to-date military hospital should be. Under the circumstances, therefore, the results of the examinations which have just taken place are remarkably good, and redound to the credit of professors and students alike. In these days of sharp and unremitting competition among medical men, both the army and navy as careers for young medical men are full of promise. Indeed, it would be no exaggeration to say that upon the whole a young man would do better to enter the army or navy medical service than to become a civil practitioner. The prizes, from a pecuniary standpoint, are not so great, but the position is assured, the life is varied and full of interest, and the opportunities for practice, and especially for scientific research, are assuredly more open to the army or navy medical officer than to the rank and file of the medical profession.

The Shiga Variety of Dysentery Bacilli in an Epidemic Near New York.

To the *Journal of Medical Research*, March, Prof. W. H. Park and Dr. H. W. Carey contribute notes upon the serum reactions obtained in laboratory investigations of cultures collected from cases of epidemic dysentery which occurred at Tuckahoe during the past summer. In July, August, and September last, there were about 350 cases of dysentery with a mortality of about 6 per cent. at the above-mentioned place. The average age of fatal cases was somewhat less than three years.

The authors summarize the result of their researches as follows: "From a fatal case of dysentery a bacillus was obtained which, in all but one of many cultural tests seemed identical with Shiga's Japan and Flexner's New Haven culture. The only point of difference being that the Tuckahoe culture produced a trace of indol in peptone solution. The specific agglutins developed in animals through infection of the group of "dysentery," bacilli, which produces considerable indol and develops acid from mannite, did not agglutinate the Tuckahoe, Shiga, or New Haven cultures. All

bacilli, so far obtained in America, Flexner's Baltimore and Philadelphia cultures, and ours from New York City and Seal Harbor—outside of the New Haven and Tuckahoe cultures, seem to belong to this class. The serum reactions of the blood, taken from a number of convalescent cases, with the Baltimore culture, were, on the average, much more marked than those obtained by us from the blood of acute cases of other intestinal diseases, and indicate that this variety of bacillus, as well as the Tuckahoe variety, was present and active in many of the Tuckahoe dysentery cases. Three months later the serum reaction had largely disappeared in the cases tested, and was about alike for both varieties of bacillus."

The conclusions come to by the authors were that not one but several varieties of the Shiga group of bacilli cause dysentery. Already two distinct varieties have been found in the intestines of those suffering from acute dysentery and colitis; which, in the opinion of the writers, are probably exciting factors in the disease. Drs. Park and Carey agree with Martin and Lentz in their statement that the Shiga type differs from Flexner's Manila-Baltimore type in cultural and agglutination reaction, but totally disagree with their assertions that one type of organism is a factor in dysentery, and the other not.

Ankylostomiasis.

Owing to the result of the investigations made by Mr. Charles Wardell Stiles in the Southern States of this country with regard to the prevalence of ankylostomiasis there, much interest has been evinced in this little-known disease. In the *British Medical Journal*, March 28, is an account of the malady by Surgeon Lieut.-Col. Oswald Baker. This writer says that the parasite—the ankylostoma duodenale—was first discovered by Dubini of Milan in 1838, and later in 1847 in Egypt, by Bilharz. Greisingier, who was working with Bilharz, came to the conclusion that it was the sole cause of the anæmia so prevalent in Egypt, known as Egyptian chlorosis. McConnel isolated the entozoön in India, where it is a prolific cause of sickness and death. Dr. Giles, who had been investigating the nature of Kala-azar in the same country, said that in his opinion the disease was simply ankylostomiasis occurring in a malaria-stricken district. In 1879 the anæmia of a progressive and fatal type, which attacked thousands of laborers working in the St. Gothard tunnel, was announced to be ankylostomiasis. The anæmia of the tropics, attributed to beriberi, malaria, general dropsy, and debility, Colonel Baker says is due to ankylostoma duodenale.

The disease is believed to exist interruptedly over three-fifths of the habitable globe. Dr. Thornhill of Ceylon states his conviction that the parasite is the greatest enemy of the human race in the tropics, with which view Colonel Baker is more or less in agreement.

The water-borne theory of infection by the ankylostoma duodenale is no longer tenable. Giles and Sandwith have both shown that this mode of infection is most unlikely. Colonel Baker says "the ova are discharged in myriads with the dejecta, and under favorable circumstances yield embryos in from one to two days. This phase of development takes place outside the body, because exposure to the oxygen of the atmosphere is essential to its accomplishment. These embryos when they gain entrance to man, quickly grow into mature parasites. Now, the inhabitants of countries wherein ankylostomiasis is very prevalent are for the most part tillers of the soil, and generally live in overcrowded villages where sanitation is unknown. They have no latrines, and ease themselves anywhere, often close to their dwellings; they are dirty in their persons, and eat food with their hands, which are unwashed, and sometimes soiled with earth containing embryos. Earth eating is too common in Egypt." This description of the habits of the Egyptian coincides somewhat closely with the manner of living followed by the lower classes in the Southern States. The conclusion, therefore, is that infection is spread by dejecta uncovered, and a generally insanitary mode of life. Dr. Loos of Cairo asserted that ankylostoma embryos entered the body through the hair follicles of the skin. Manson, however, is not prepared to endorse Loos's views.

The writer in the *British Medical Journal* thinks that, in view of the marked changes found in the liver in post-mortem examinations, the question of the ankylostoma being capable of producing a toxin which has hæmolytic and other destructive properties, must be briefly considered. Some observers maintain that such is the case, and to support their views appeal to the analogous action of the bothriocephalus latus, which, although not a blood-sucking parasite, generates a blood toxin which causes profound anæmia.

As to the means of prevention, Colonel Baker says these are summed up in the word sanitation. Burial of the excreta would quickly stay the spread of the disease and ultimately stamp it out. For the treatment of ankylostomiasis there is no vermifuge comparable to thymol. Treated early the malady is easily cured, but neglected it tends to a fatal issue. Therefore, the dejecta of all persons who are received into hospitals, jails, and asylums in the tropics should be searched for the ova of the parasite, and the diagnosis of no tropical disease associated with anæmia should be considered complete until this investigation has been made.

Philadelphia Pediatric Society.—At a stated meeting, held April 14, Dr. G. G. Davis exhibited two patients showing results of bloodless operation for congenital dislocation of the hip. Dr. DeForest Willard presented skiagraphs illustrative of a variety of cases of congenital dislocation of the hip treated by operation. Dr. James K. Young reported the case of a patient with double congenital dislocation of the hip. Dr. Young also reported the case of a patient with spastic paraplegia improved by operation. After tenotomy not only was the patient able to get about better, but there was also an improvement in the mental condition. Dr. William G. Spiller exhibited a patient with Little's disease, and also a patient with family spastic paralysis spinal, both of whom were improved by operation. Dr. Edwin E. Graham reported a case showing the non-susceptibility of the newborn to measles. Although the mother was suffering from the disease at the time of birth and the child was not separated from her, the latter escaped entirely. Dr. Graham reported also a case of pertussis with unusual cerebral symptoms. The patient was a child in whom sopor and finally coma developed in the sixth or seventh week of an attack of whooping-cough. Intracranial hemorrhage was at first suspected, and later meningitis. Lumbar puncture was performed, but yielded no definite information. After death lesions suggestive of tuberculous meningitis were found.

News of the Week.

Prof. C. A. Ewald of Berlin is on a visit to this country, and has been the recipient of many courtesies from his numerous professional friends. While in New York he will be the guest of Dr. Max Einhorn, and will, at intervals, visit Washington, Baltimore, Philadelphia, and Boston, returning home the latter part of this month. On his arrival here on Wednesday, a luncheon was given in his honor at the University Club by Professor Osler of Johns Hopkins, and a dinner the same evening by Dr. Einhorn, at the latter's residence, after which the distinguished foreigner read a paper before the German Medical Society on "Gastric Crises." Next week he will read a paper before the Congress of American Physicians at Washington, after which he will visit the other cities mentioned. As his main object is recreation, he will doubtless have abundant opportunities to prove how warm will be his welcome by his many American admirers.

At the dinner given by Dr. Einhorn there were present besides Mesdames Ewald and Einhorn, Drs. Wm. Osler and J. C. Hemmeter of Baltimore, W. G. Morgan of Washington, C. G. Stockton of Buffalo, Drs. A. Jacobi, L. Weber, A. Caillé, Willy Meyer, E. Quintard, and Geo. F. Shrady of this city.

Doukhobors Marching Again.—A dispatch from Winnipeg, Man., dated May 2, says that fifty half-naked Doukhobors are on the march for Saskatoon. The first detachment was reported at Elbow Village, twenty-two miles from home, on the night of May 1, where the head man was trying to persuade them to go back home. They say they are searching for Jesus, and will not stop until they find Him. The men have discarded their trousers and are marching in their boots and coats, shouting and singing.

The Rapid Growth of New York City.—The population of New York City is increasing at a remarkably rapid rate. The birth rate is now 5 per cent. higher than the death rate, and a large proportion of the phenomenal immigration which has been coming to New York of late remains there. The population of the city is now estimated by the Board of Health at 3,687,000, a gain of 250,000 in the three years since the census was taken. Of this gain 90,000 was in Manhattan, 50,000 in the Bronx, 90,000 in Brooklyn, and 20,000 in Queens. The gain in population in Richmond is but slight.

A $25,000,000 Pure Milk Company.—The People's Pure Milk Company of New York City was incorporated on May 2 with a capital of $25,000,000.

Cholera at Manila.—A cable despatch to the *Sun*, dated May 3, announces that cholera is gradually increasing throughout the archipelago, concurrently with the return of the hot season. The deaths from the disease in Manila itself average twenty weekly. The health authorities have strengthened the guards employed to prevent the contamination of the water supply.

The Columbia Literary Monthly on Athletics.—This magazine for May contains a long editorial article devoted to the question of athletics as carried on in Columbia College. The article is a trenchant, and in many respects a well-written, attack on the position which is accorded to athletics at Columbia. It deprecates the extreme worship of the strenuous life with which students at colleges nowadays appear to be imbued, and suggests that love for athletics is being carried too far among American college students. True enough.

The Goodsell-Bedell Bill and Sanatoria.—A letter has been sent to Governor Odell, by the New York Charity Organization Society's Committee on the Prevention of Tuberculosis, requesting him to veto the Goodsell-Bedell bill. The letter draws attention to the fact, that the effect of this bill becoming law would be to render it impossible for a city of the first class to erect a sanitarium outside its own limits under the laws of 1900 authorizing such action. The bill, however, goes far beyond even this, and would equally interfere with any hospital, camp, or sanatorium which might otherwise be erected by a private philanthropist, a fraternal society, or any other association or corporation.

Drug Stores Reopened in Havana.—It is reported, in the New York *Tribune*, that the druggists in Havana reopened their stores on May 2, on the understanding that no tax will be levied on patent medicines for fifteen days. It is probable that the dispute between the druggists and the government will be settled without further trouble.

Philadelphia Neurological Society.—At a stated meeting, held April 28, Dr. John K. Mitchell exhibited a case of poliomyelitis in an adult involving all four extremities. The patient was a young man, twenty years old, who, following loss of consciousness and a febrile attack eighteen months before coming under observation, was completely paralyzed, with preserved sensibility. There was gradual though imperfect return of power first in the head, then in the right arm, next in the left forearm, and finally in the left thigh and the right leg. The knee-jerks and the cremasteric reflexes were absent, the plantar and the abdominal reflexes diminished. The muscular responses to electric stimulation were diminished, without degenerative reaction. Under treatment, principally with massage, movements, and electricity, improvement took place slowly but steadily. The case was shown on account of the widespread and irregular distribution of the paralysis and of the age of the patient. Drs. Wm. G. Spiller and T. H. Weisenburg reported a case of brachial palsy in an adult, resulting from a lesion of the spinal cord; and they exhibited a man suffering from tuberculosis and presenting paralysis of the forearm with wrist-drop and painful swelling of the wrist-joint. Dr. Horace Carncross exhibited a case of Thomsen's disease associated with pseudo-muscular hypertrophy. The patient was a young man of about twenty-two years, who weighed fifteen pounds at birth and remained abnormally large during childhood. Later the muscles in the upper extremities underwent wasting, while those in the lower extremities remained large, though not correspondingly strong. In addition, the patient had difficulty in initiating movements, the attempt being attended with a certain degree of resistance, which diminished as the movement was continued. The response of the muscles to electric stimulation was slow and sustained. The mother had for a time presented some intermittent spasm of the muscles of the face. Dr. Alfred Gordon read a paper entitled "A Note on the Periodic Insanities, with the Report of Three Cases of Intermittent Melancholia." He pointed out the tendency on the part of intermittent or recurrent melancholia to set in and also to terminate rather abruptly. Dr. Wm. Pickett prerented a communication entitled, "Senile Dementia: A Statistical Study of Two Hundred Cases, with Special Reference to Types of the Disease."

The Death of Dr. Hugo Lupinski.—At a meeting of the Academy of Medicine of Grand Rapids, Mich., the following resolutions were adopted:

"In the prime of manhood, at the zenith of his success, in the midst of a wide field of usefulness and

endeavor, Dr. Hugo Lupinski departed this life April 7, 1903; and,

"*Whereas*, In the death of Dr. Lupinski the Academy of Medicine of Grand Rapids, as a whole, and individually, has suffered an irreparable loss, in that his loyalty to the principles upheld by the Academy was unflinching, and his ability as a scientific physician lent value and dignity to its meetings; and,

"*Whereas*, The community at large, as well, has lost a true citizen and a faithful public servant, possessed of strong convictions and the courage of them,

"*Be it therefore Resolved*, That we, the Academy of Medicine and members of this community, do hereby express our sense of loss and sorrow, in a full realization of the good works and noble traits of character of our lamented colleague and brother; and,

"*Be it Resolved*, That these resolutions be spread upon the records of the Academy, and that copies be furnished to the medical press, within the judgment of the secretary of this society, and to the sorrowing family of Dr. Lupinski, in evidence of our sympathy and grief.

(Signed) Charles E. Hooker, M.D., Chairman;
Henry Hulst, M.D.,
Perry Shurtz, M.D.

Philadelphia County Medical Society, South Branch.—At a stated meeting, held April 24, 1903, Dr. Jos. M. O'Malley reported a case of ulcerative endocarditis and he exhibited the heart. Dr. J. H. Musser presented a communication entitled, "The Diagnosis of Endocarditis." Dr. J. C. Wilson, a paper entitled "The Treatment of Endocarditis," and Dr. A. E. Roussell, a paper entitled "Septic Endocarditis."

American Medico-Psychological Association.—The fifty-ninth annual meeting of the American Medico-Psychological Association, late Association of Medical Superintendents of American Institutions for the Insane, founded in 1844, will be held at Washington, in affiliation with the Congress of American Physicians and Surgeons, May 12, 13, 14 and 15.

Obituary Notes.—Dr. James Conland, aged fifty-two years, died at his home in Brattleboro, Vt., on May 2, from nervous exhaustion and heart disease. Dr. Conland was born in Brooklyn, N. Y., and graduated from the medical department of the University of Vermont in 1878, and practised in Brattleboro for a large part of his professional life. Dr. Conland was a great friend of Rudyard Kipling, who owned property and spent several summers in Brattleboro. The deceased physician is said to have greatly assisted the English author in the preparation of "Captain Courageous," and, among a rare collection of first editions, possessed the manuscript of that work.

Dr. James A. Roache died at his home, 312 Jefferson avenue, Brooklyn, N. Y., on May 3. He was born in New York City in 1869, and went to Brooklyn in 1873, where he studied at St. Patrick's Academy, and later in St. Francis's College, and in 1891 was graduated from the Long Island College Hospital, while for a time he was an interne in St. Mary's Hospital. At the time of his death he was one of the visiting physicians to that institution. In 1899 Dr. Roache was married to the youngest daughter of ex-Register Hugh McLaughlin, the leader of the Kings County Democracy.

Dr. Harris Lee Paige, aged forty-five years, died at Dover, Del., on April 30, in an attack of apoplexy. He was a graduate of Jefferson Medical College.

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent.)

PUBLIC HEALTH—MISTAKES IN DIAGNOSIS—DANGERS OF HYPNOTICS—VELVRIL—LYSOFORM—JURYMEN ON DOCTORS—RURAL MIDWIVES—SMALLPOX—COUNTY COUNCIL AND PATHOLOGISTS—NEWSPAPER SCIENCE AND MEDICINE—DEATHS.

London, April 17, 1903.

The unusually mild winter we have had seems to have had a beneficial influence on the public health. The returns for the first quarter (thirteen weeks) of the present year show a death rate for the seventy-six greater towns of 17.3 as against 19.9 for the corresponding quarter of last year. London's mortality has been exactly the same, but some of the suburban rates have been remarkable—ranging from 9.1 at Hornsey to 16.6 at West Ham.

To balance the winter we have, so far, a cold spring. The Easter holidays were spoiled to many by an unexpected cold snap—particularly those seeking out-door amusements. In Buckinghamshire eight degrees of frost with strong wind has ruined the hopes of a good fruit crop, and farther north snow and frost have caused heavy loss to the flock masters as the lambing had begun. Yesterday, in London, we had several snow showers with cutting wind, and this morning I learn that further up the Thames valley twelve degrees of frost were registered during the night—a most unusual fall.

The study of mistakes is a profitable one, whether our own or other people's. Perhaps the latter is the more attractive. A part of this extensive subject, viz., mistakes in the diagnosis of malignant disease, was brought before the Harveian Society on the 2d inst. by Mr. Raymond Johnson, who set out with the remark that these mistakes are often due to the primary tumor being overlooked and a symptom caused by a secondary deposit taken for the disease. A case of this kind was that of a woman with paralysis and muscular atrophy of the upper limbs, the nature of which was doubtful until a small, hard nodule was accidentally discovered in one breast. At the autopsy many secondary growths were found, and one in the spine involved nerve roots, which explained the symptoms. He showed a tumor of the upper end of the humerus, from University College Museum, which had been diagnosed as sarcoma and amputation at the shoulder performed. The microscope showed it to be carcinoma and the patient was found to have cancer of the uterus. Spontaneous fracture of bones may be due to secondary carcinoma in a central position and so causing no swelling. Abdominal tumors present other difficulties. Mr. Johnson mentioned inflammatory deposits simulating hard tumors, localized peritonitis again, gallstones, psoas abscess and other conditions. He referred to a case of abdominal section revealing a large retroperitoneal tumor with the appearance of sarcoma. A history of epistaxis and "blood in the joints" suggested the possibility of an extravasation due to hæmophilia. For months altered blood oozed from an opening in the incision and the tumor gradually disappeared, the patient being quite well four years afterward.

Mr. Johnson's paper evoked the relation of other cases, in some of which the diagnosis seemed to have been too gloomy, though in others the reverse error had occurred. Dr. James Taylor said he knew of one patient supposed to be certainly dying from cancer, but who is now quite well. Dr. Prickett mentioned the case of a lady of seventy-three years with fetid discharge and a mass thought to be undoubtedly malignant, extending from the cervix to within an inch of the vulva, and considered too advanced for operation. In less than a year it was gone. Either the diagnosis was wrong or malignant growths sometimes disappear spontaneously. Mr. Malcolm instanced an operation on a child of four years for tumor of the kidney which proved to be sarcoma of the tail of the pancreas. After death a secondary growth was found within the portal vein. In another case, supposed to be gallstones, cancer of the head of the pancreas was revealed at the operation, and at the post-mortem, five weeks later, the duodenum seemed a tube of cancerous tissue. In a case of supposed ovarian tumor, the peritoneal cavity was found on operation completely obliterated, so nothing could be done, but eighteen months later there was no tumor to be detected and the patient was quite well. In another, inflammatory disease of ovaries and tubes was diagnosed; the pelvis was found shut off by adherent intestines; an opening was made through the posterior vaginal fornix, but no pus was found in the hard, pelvic mass which was then looked upon as cancerous, but a few months later it had disappeared and the patient was quite well.

Our new Therapeutical Society is proving a vigorous

infant and we may hope for it a longer life than its predecessors. Several interesting communications respecting little known remedies have been submitted for examination. At the last meeting a collection of roots from Lake Nyassa was exhibited. In due time we shall hear more of these, as the society resolved to publish abstracts of papers and proceedings. Under the fostering care of the Society of Apothecaries there is promise of success.

The Master of the Worshipful Souls, Mr. W. Parson, presided at the meeting on the 31st ult., elections to the council were confirmed and then Dr. Nestor Tirard read a paper on "Some Dangers of Hypnotics." He said all, both old and new, involve danger. The conditions under which untoward results occur not being solely dependent on the dose. The danger may be limited to the patient, but the blame may be laid on the prescriber or dispenser. Dr. Tirard quoted a therapeutic index which gave fifty remedies for insomnia, many, of course, but little known, but the majority were spoken of as producing refreshing sleep without depressing circulation or respiration, though later on some toxic effects might be mentioned. He held that all might be dangerous. Sulphonal long held its ground as safe, if slow and somewhat uncertain; later came accounts of giddiness, drowsiness, headache, ataxic gait, collapse, and other serious effects, which often set in after the patient had apparently been benefited by previous doses. So with trional and tetronal, the toxic effects may suddenly set in after the prolonged use of moderate doses. Paraldehyde, the taste of which is to many very disagreeable, has nevertheless led to a habit and produced deterioration comparable to chronic alcoholism. The presence of certain diseases may render ordinary doses dangerous *e. g.*, chloral in cardiac degeneration or dilatation. Instances were given of poisoning under different conditions. In one case a bottle which had contained 250 gr. of sulphonal was found and the patient remained unconscious for a week, although prompt treatment was obtained. Other cases arose from the patients increasing the doses prescribed; one was named in which he deliberately altered his prescription. Cases have also unfortunately occurred in which blame has attached to either prescriber or dispenser. It is further a common trick of *habitués* to keep their narcotic in a bottle labeled with an innocent name. One person had solution of morphine labeled sal volatile, and a nurse gave it with fatal result. The hypodermic syringe became full of risks when it passed into the hands of the public, and the difficulty of treating a case of overdose thus given was pointed out by Dr. Tirard. Seconding him in that, I would add that there is danger in leaving this instrument to be used by nurses. I have always held that doctors are too ready to hand over some of their work to nurses. They have seen it done in hospitals and have imitated their teachers. But even in hospitals there is more of this than there ought to be. Dr. Tirard would only permit hypnotics to be dispensed on a freshly-dated prescription, which should be retained and returned to the prescriber. In the discussion on this paper. Dr. de Haviland Hall mentioned the difficulty that patients insisted on sleep being procured at any price. In a case where $\frac{1}{10}$ gr. of atropine was given for opium poisoning he recommended the dose to be reduced to half, and the attendant gave $\frac{1}{20}$, thinking that the half of $\frac{1}{10}$. The patient died.

A second paper was then read by Mr. Peyton T. B. Beale on the new aseptic film called "Velvril," which is a mixture of nitro-cellulose with a nitrated oil and is soluble in acetone, but not in most other liquids. The skin being washed with acetone may be painted over a wound with a solution of velvril and the film pressed firmly on it with dry sterile wool and a bandage. Left thus it will peel off in ten or twelve days, but it can be removed any time by laying a damp cloth on it for a few minutes. Velvril was said to be absolutely impervious to all ordinary liquids or gases, never to harden and to be unchanged by sterilizing in boiling water, but the solution in acetone is itself sterile and unirritating. It was suggested that it be used for bougies and catheters and replace india rubber in surgical practice.

I am reminded by Mr. Peyton Beale's communication that he has for some time been using lysoform at King's College Hospital as an antiseptic and bactericide. For sterilizing the skin this fluid may be rubbed in for two or three minutes. It makes a lather and can be washed off with sterile water. As a deodorant in gangrene, etc., it is most powerful in a strength of 1 in 40. As a gargle or mouth-wash 1 in 60 is enough. With pus it forms a thick ropy fluid, which can be washed away with water. A plug soaked in 1 in 20 left in a burrowing abscess or sinus for a few hours will effectually cleanse it.

At an inquest on Saturday the jury wished to censure a doctor for refusing to go to a stranger in the night until paid. The coroner, who was a doctor, explained that people had no more right to demand the services of a medical man without payment than to require the baker or butcher to supply them. He said every holiday time medical men get called out with a tale that somebody has poisoned himself or is injured, and on arrival find that nothing but a drunken brawl has occurred, and gets nothing for their trouble. "I have been through the mill and know," he added.

At another inquest some of the jury expressed indignation with a doctor who had been called in to treat the deceased for an overdose of opium. There was no evidence, favoring suicide, but these jurymen thought the doctor ought to have called in the police!

Mrs. Heywood Johnstone, who describes herself as "Chair*man* of the Rural Midwives' Association," is appealing for funds to pay the secretary pioneer and visiting superintendent to set this organization at work to train and provide midwives for the villages. You will remember that Mr. H. Johnstone was the leader of the party which forced the Midwives' Bill through Parliament in opposition to the voice of the great majority of the profession.

Local outbreaks of smallpox in the provinces are still giving rise to uneasiness among sanitary authorities.

The County Council has written to the chief hospitals respecting its scheme of employing skilled pathologists at inquests. Guy's has already answered pointing out that in difficult cases the pathological expert would be valuable, but that it should not supersede the clinical medical evidence, and that the fee of two guineas would not secure the services of pathologists of the required standard.

The "Mystery of Radium" is the subject of some correspondence in the *Times* of more or less interest, according to the point of view of the reader. Various theories are being put forward to explain what little we know about radium, most of them with a confidence that takes for granted our knowledge is complete. But scientific men are not indulging in any such supposition.

When the newspapers take up medical or scientific matters they are often amusing. One of them has just reported that the authorities of St. Bartholomew's Hospital have discovered that patients who could afford to pay resort to their out-patient department, and have therefore put up a board saying inquiry will be made as to the circumstances of applicants. Bart's men who remember that board for some quarter of a century are amused.

Another paper came out the day before yesterday with a statement that the Royal Commission on Cancer would shortly report in favor of treatment by high frequency currents. As there is no Royal Commission on Cancer in existence, this is early news indeed.

Deputy Surgeon-General G. B. F. Arden (M.R.C.S., 1854) died at sea on the 1st instant, on his way home from Madeira. He served in the army from 1854 to 1879. He was through the New Zealand war (1863-6), for which he had the medal.

Dr. James Priestley died on the 31st ult. of septicæmia, contracted in the course of his professional work. He was only thirty-eight years of age, but he had made his mark. He took his B.A. in 1886, M.B. in 1894, and M.D. of the Royal University of Ireland in 1897, having taken the Public Health diploma of the English Colleges in 1893. He was for some time assistant medical officer in Paddington, and afterward senior of the N. E. Fever Hospital of the Asylums Board. Five years ago he went into private practice at Lee-on-the-Solent where he had attained success and the esteem of his neighbors.

Dr. J. Glen Forsyth, Assistant Medical Officer of the West Riding Asylum, Wakefield, died on the 11th inst., after a few days' illness. He took his M.B., Ch.B. Edin., in 1899.

OUR LETTER FROM THE PHILIPPINES.

(From Our Special Correspondent.)

A CHINESE MEDICAL INSPECTOR—SOME ACCOUNT OF SURRA, THE HORSE DISEASE—THE MANILA MEDICAL SOCIETY—RECOVERY FROM PISTOL SHOT WOUND OF INTESTINE.

To facilitate its work among the 60,000 Chinese residents of Manila, the Board of Health has appointed a Chinese physician, Dr. Han Kee, as Medical Inspector. Dr. Han Kee is a graduate of the English Medical School at Hongkong, and is said to be well qualified professionally in the practice of scientific medicine. He will also be the medical superintendent of the Chinese hospital in Manila. It is believed that he will have an excellent influence with the Chinese element here, since he is of their own race and can approach them in their own language.

In deference to the opposition of the Chinese to cremation as a method of disposal of the dead, and to secure their support as far as possible in matters of sanitation, the health authorities of Manila will hereafter furnish metallic coffins gratuitously in the case of Chinese dying

of plague, so that the bones of the deceased may ultimately be removed to China for burial, according to Chinese custom. Bodies must be packed in quicklime in hermetically sealed metal coffins and be buried for a term of years before removal. As plague is occurring only in the poorer class of coolies, the friends and relatives of those who have died of this disease are frequently too poor to buy the sanitary coffins required, and hence the health authorities have decided to furnish the latter without cost in plague cases among the Chinese.

Americans who have just returned to Manila from the island of Panay state that cholera has been stamped out, but that malarial fever has taken its place and the number of deaths from the latter disease is very large. Much of this sickness is the result of the ignorant superstitions entertained by the natives regarding the alleged poisoning of the wells by the Americans during the cholera epidemic. As a result, American missionaries who are conducting free dispensaries in connection with their other duties find it a matter of much difficulty to induce the natives to accept and use their medicines. Malaria has thus become very prevalent and the officials find considerable difficulty in dealing with the situation.

Major-General Davis, commanding the army in the Philippines, has sent out a party to explore the mountains near Mariveles, at the entrance to Manila Bay, with a view of finding a site for a convalescent hospital above the 2,500-foot level. Many of the mountains near the bay are 3,000 to 4,200 feet high, and the present inaccessibility of the government sanitarium at Benguet raises the question as to whether a suitable locality for a convalescent hospital cannot be found near to Manila.

To facilitate sanitary work in the islands, the status of provincial and municipal health officers has been changed. Hereafter they will be regarded not as purely local officials, but as officers of the general government, and as such will be liable to transfer for duty to other provinces or towns as need arises. This change was made largely as a result of the cholera epidemic, when it was found difficult to displace local officials of inferior qualifications, who had not yet had experience with cholera, by better men who had had ample experience in this respect. The change will not be favorably regarded by those affected, as they are chiefly Filipino physicians who have outside practices in addition to their other duties, and these practices they will be loth to surrender.

A report on surra, the horse disease so prevalent here, written by Veterinarian Evans of the British Indian Army, has just been published by the military authorities here. The report forms part of the material being collected relative to surra by a commission of line officers now travelling in India and the Dutch East Indies investigating this disease which during the past year destroyed about one-fourth of the cavalry horses in the Philippines, besides a vast number of native ponies. The disease has lately been studied by our own army surgeons, who have proved the inoculability of the disease, discovered the specific microorganism in the blood, traced this microorganism through a biting fly, and identified the fly. In view of the acquirement of so much data on the subject, upon which proper measures of prophylaxis can be intelligently based, it seems unfortunate that the present report should have been selected for the stamp of military approval, when it is so "mixed" in its pathology and in respect to the method of transmission of the disease. The report states, in addition to many facts of no value and some misinformation with regard to the disease, that surra is characterized by a specific infusorium found in the blood, is incurable and transmissible by inoculation. It exists in India chiefly in the rainy season, from June to November, and is rarely seen in the spring. It is confined to certain districts, and animals removed from those districts before the surra season escape the disease. The necessity for the cleaning up and destruction of horse manure around stables and old camping grounds is insisted upon. A biting fly, of undescribed species, is found in the surra districts during the surra season. Veterinarian Evans still clings to the old idea that surra is in some way transmitted through impure water or on green forage cut on marshes soaked with stagnant and foul-smelling water. He consequently bases his prophylactic measures on this belief and completely ignores measures calculated to limit the disease by preventing inoculation through the agency of biting flies, which are at present the only known medium for conveying the infection.

The program of the February meeting of the Manila Medical Society included interesting papers by Dr. William B. Wherry, on the sterilization of drinking water by the use of benzozone, and by Dr. H. W. Yemans, on personal hygiene in the tropics. The tests relative to the sterilization of drinking water was carried out as a result of the excessive expense connected with the supply of distilled water to the San Lazaro Hospital. Dr. Wherry used benzozone in 1-1,000 solution, and found that all non-sporulating bacteria present in the city water supply were destroyed by a strength of 1-60,000, acting over a period of five minutes. Experimenting with the typhoid bacillus as a type of the less resistive organisms, to which class the cholera bacillus and Shiga's dysentery bacillus also belong, it was found that sterilization invariably occurred in five minutes, where sufficient benzozone solution was added to 300 c.c. of sterilized water to which 1 c.c. of a fresh bouillon culture of typhoid bacilli had previously been added. It was stated that the saving which could be effected by the use of benzozone in relation to the drinking-water supply of San Lazaro Hospital alone would amount to more than $200 per month. The use of benzozone has no unfavorable effect upon the organism, even when acting over long periods of time, and does not render the water to which it has been added unpalatable to the taste. Ever since the beginning of the cholera epidemic benzozone in 1-2,000 solution has been used by a number of persons for all drinking purposes. In spite of the favorable bacteriological tests for the sterilization of drinking water by the use of benzozone, it should not be forgotten that the chief water-borne disease in the tropics is amœbic dysentery, and that the effect of benzozone upon the lower forms of animal life has not yet been worked out. The simple plan of boiling all drinking water is also the most safe. While the use of benzozone might seem to have a certain value for military use, the rapidity with which it decomposes would seriously interfere with its transportability and hence its value for this purpose. As an intestinal antiseptic, benzozone has much value, since it is the most powerful germicide known. The manner in which it destroys bacteria is not understood, since although it is known to possess oxidizing powers, these are only about one-sixtieth as great as in the case of hydrogen peroxide, which has much less effective germicidal powers.

Dr. Yemans, in his paper on personal hygiene in the tropics, placed special stress on the necessity of avoiding chilling at night in the prevention of congestive diarrhœas. He urged the use of a more loose and rational dress, particularly among the white women, many of whom wear corsets. He believes that the too free use of soap and friction with towels is an important factor in the occurrence of skin diseases of a parasitic nature among foreigners, the soap macerating and removing the superficial epidermal layer while the friction with rough towels produced minute lesions upon which the microorganisms of parasitic skin disease found favorable conditions for their multiplication and development. The common use of imported carbonated table waters by Americans was deprecated as being largely responsible for the constipation so commonly found among foreign residents—in many instances the use of plain boiled water, in lieu of carbonated waters, was found to effect a complete cure in many cases of obstinate constipation without the necessity of resorting to medication. Much of the constipation existing at present among foreign residents is due to the disuse of fresh fruits and vegetables as a result of the existence of cholera.

Dr Banister of the army, exhibited a patient in whom recovery had followed laparotomy for pistol shot wound of the intestines; and Dr. McDill showed a fifty-pound multilocular ovarian cyst and a large dermoid cyst which he had removed from the same patient, a young Filipino girl. In connection with these two cases, the president of the society, Dr. Donelan, an English physician long resident in Manila, stated that to his knowledge a laparotomy had never been performed in the Philippine Islands prior to the coming of the Americans, except a few cases of Cæsarian section performed by the Spanish friars on the dead body to enable baptism of the fœtus. The influx of a high class of medical men with the American army had been of the greatest value in raising the standard of scientific medicine and operative surgery in the islands.

Prolapse of the Posterior Vaginal Wall.—Roche reports the case of a woman of thirty-nine years. She was the mother of five children. Cough caused a small vulvar tumor, the size of a mandarin. Urination was frequent, and there was incontinence on laughing or exertion. There was a very marked projection of the posterior vaginal wall. Rectal touch showed that the rectal wall had not followed the vaginal wall. There was a narrowing of the rectum, annular, with irregular walls. The uterus was small and anteflexed. The fact that the rectal wall did not follow the vaginal is quite rare. It is probably due to the presence of the narrowing. This contraction was bacillary in origin.—*Journal de Médecine de Bordeaux*, April 5, 1903.

Progress of Medical Science.

The Boston Medical and Surgical Journal, April 30, 1903.

A Case of Juvenile Aortic Stenosis, with Subsequent Insufficiency; Sudden Death; Autopsy.—Albert N. Blodgett describes the case of a young man of twenty years who was under observation for two and a half years. His pulse was 58 to 60, suddenly relaxing under the finger. Clinical symptoms pointed to cardiac affection, which was confirmed by physical examination. The patient fell dead while boxing with a college companion, having received only a moderate blow on the side of the face. At the autopsy the diagnosis was made of chronic aortic endocarditis with stenosis of the opening; hypertrophy of the left heart, and general venous engorgement. The author attributes the affection to the results of a syphilitic affection of some years before, the traces of which were still distinctly visible. There was no history of rheumatism or any other infective disorder to which the lesion of the heart could be ascribed, and it was certainly not congenital.

Albumosuria.—Chauncey Rea Burr says that albumosuria is the term used to describe that condition in which albumoses are present in the urine. It is a pathological state, and its importance has been but dimly appreciated till very recently. Clinically, albumosuria is found where there is leucocytosis; it is highly probable that a large part of the albumoses present in the blood of febrile cases is derived from the leucocytes. The author gives directions for the detection of the various forms of albumoses present in the urine. He also gives a list of the diseases in which they are found. Albumoses are toxic; cobra venom consists of 98 per cent. of albumose and peptone and 2 per cent. of globulin. Its toxicity resides in the albumose. The treatment of albumosuria and peptonuria is, in general, that which is employed for the septic state. The neurotoxic element is best combated by oxygen and strychnia. The best method of administering oxygen is by the ingestion of a new chemical compound, magnesium dioxide. Another agent of value is normal salt-solution, administered preferably in rectal injections of a pint or half a pint morning and night, the bowels having previously been emptied by an enema. The author, in closing, lays emphasis on the fact that, apart from lesions of the digestive tract, albumosuria is indicative of leucocytosis, and peptonuria of pus absorption.

Strangulated Hernia in an Infant Six Weeks Old; Operation; Recovery.—George Tully Vaughan reports the case of a colored male child in whom a tight swelling about the size of a hen's egg was seen in the scrotum and inguinal region. Operation was decided on, and about eighteen inches of ileum were found in the sac of the tunica vaginilis testis, highly congested, with a portion adherent to the bottom of the sac. This portion looked almost gangrenous in patches. The constriction was at the internal ring, and this had to be slightly enlarged before the intestine could be reduced. The peritoneum and transversalis fascia were sewed across with kangaroo tendon as high up as possible, the cord was raised from its bed and one suture introduced to bring together the conjoined tendon and Poupart's ligament, the cord replaced, and the aponeurosis of the external oblique and fascia united over the cord by a continuous kangaroo tendon suture. The skin was united with continuous silkworm-gut suture and sealed with collodion. No attempt was made to dissect the funicular process of the peritoneum from the cord—it was simply closed above by means of a kangaroo tendon suture carefully inserted so as not to injure the cord. There was no further trouble, no vomiting nor excessive crying. The stitches were removed eleven days after the operation and the patient discharged well five days later.

New York Medical Journal, May 2, 1903.

A Case of Nævus of the Scalp and Nose Treated by Hot-water Injections.—F. Griffith reports the case, his patient being a girl of seven months. The scalp area involved was first treated by injection of water at a temperature of from 180° to 200° F. One fluid drachm was injected without any anæsthesia. A dry dressing was applied, held in position by thin india-rubber straps. In a few days the original swelling had almost entirely disappeared. Subsequent injections completed the cure. The nasal area was then treated in the same way. In neither instance was the skin-surface damaged by the heat of the injections. The chief danger following the employment of this method of treatment is that of embolism, but this tendency seems to be overcome by having the water near the boiling point when injecting, thereby insuring prompt and firm coagulation.

The Tendo Achillis Shortened for the Restoration of the Function of the Calf, Lost as a Result of a Previous Tenotomy.—R. A. Hibbs reports three cases illustrating his paper with some excellent photographs. The facts revealed by the operations in these cases for shortening the tendon, viz., the dissimilarity in every important particular of the structure filling in the gap between the ends of the old tendon to normal tendon, may be considered unmistakable evidence that the subcutaneous division of the tendo Achillis is not always so successful as it has long been considered to be; that while in some cases the healing process seems to reproduce a structure sufficiently strong to perform the function of tendon, in others exactly similar, it does not do so, and that one cannot be sure in a given case what the result will be. Therefore, there must be some condition or conditions necessary in order that the healing process may be entirely successful, which cannot be secured with certainty by that operation, and Hibbs is convinced that they are: (1) The preservation of the sheath. (2) The preservation of the continuity of the tendon. And these cannot be secured except through an open operation.

The Operative Treatment of Stenosis of the Larynx Following Intubation and Tracheotomy; Report and Exhibition of Cases.—A. B. Duel emphasizes the following points: (1) The largest sized tube possible should be inserted, under an anæsthetic. In case of contraction, rapid dilatation should be done by beginning with the small sizes and working up to the large special tube, which is to be left in place. This special tube should be as large as can be inserted, and the constriction below the neck only $\frac{1}{32}$ of an inch smaller than the retaining swell. (2) This tube should be left in, undisturbed, for six weeks at least. It should then be removed, and, if a cure has not been accomplished, it should be replaced for six weeks longer. The trouble in these cases is that autoextubaton and frequent reintubation defeat the purpose of the tube by constantly irritating the larynx. Duel is therefore in favor of splitting the larynx and holding the tube in place by means of the retaining clamp early, in such cases, rather than of resorting to a tracheotomy, which, almost invariably adds cicatricial bands to the already existing hypertrophy. In patients who have already been tracheotomized for a considerable time, so that bands have already formed, these constrictions should, if possible, be gradually dilated, and the special tube be then allowed to remain. Should it be impossible to dilate, however, or should autoextubation take place frequently after dilatation, a thyreotomy should be done and the tube be held in place.

The Treatment of Gastric and Duodenal Hemorrhages.—Max Einhorn says that we should first check the bleeding and then combat the disease underlying the hemorrhage. General measures include rest in bed, total abstinence from food and drink and opiates subcutaneously or per rectum. Rectal enemata will furnish proper nutriment. Saline infusions subcutaneously or per rectum are of service. Ice-bags may be applied to the abdomen. Ergot may be given by the hypodermic method. Injections of gelatin are often useful. It may be given by the mouth in the forms of calfs-foot jelly. Einhorn prefers the subcutaneous route, injecting about 100 c.c. of a two-per-cent. solution into the gluteal region. Adrenalin is also of service. Surgical measures are of two kinds—first, the location of the bleeding area and excising or cauterizing it, and, second, performing a gastroenterostomy. The indications for surgical intervention are thus summarized: (1) Very profuse hemorrhages recurring at comparatively short intervals (two to three days) demand immediate operation. (2) Profuse gastric, and especially duodenal hemorrhages, occurring once or twice yearly with more or less regularity, and each time greatly endangering the life of the patient, require an interval or, so to say, prophylactic operation, to avoid a return of the hemorrhage. (3) Frequent small hemorrhages of the stomach or duodenum which greatly debilitate the patient and cannot be stopped by rational therapeutics, often demand operative measures. Here, also, a gastroenterostomy will generally be employed.

Journal of the American Medical Association, May 2, 1903.

The Meaning and Significance of Leucocytosis.—The views of R. N. Willson are summarized in the following statements: (1) The term leucocytosis must include every increase in the absolute number of the leucocytes of the blood examined, as well as every increase in the percentage count of the various leucocytic forms. (2) A leucocytosis, of whatever nature, must always be regarded as a clinical sign of importance, but never of such weight as to influence against equally convincing physical signs. (3) A high percentage of the polymorphonuclear forms in the absence of an absolute leucocytosis indicates the presence

either of pus or of some grave inflammatory process, together with a low vitality of the patient. (4) Specific factors may rarely exert such an unusual influence as to interfere with the customary reaction of the polymorphonuclear cells. At least one instance has been noted in which the total number of leucocytes was increased at the same time, with a marked reduction in the number of the polymorphonuclear forms. This condition is, probably, seldom encountered. (5) Single counts of the leucocytes, or single estimations of the leucocytic percentages are often misleading; while a persistent series of observations will seldom fail to aid in the diagnosis and treatment of the condition. (6) A gradual, but steady, rise in the total count of leucocytes above the customary number usually indicates the presence of an active and augmenting inflammatory influence. When this increase reaches large proportions it may be looked on as an indication of the presence of an active leucocytic process (seroses or purulent effusion, localized pus collection, pneumonic exudate, etc.), provided the clinical picture also bears out the suggestion.

Is the Consumptive Chest Flat?—From a study of over 350 cases, Woods Hutchinson presents the following deductions: (1) The typical tuberculous chest is round instead of flat, and has an average index of about 80, nearly 10° above the normal. (2) This type of chest precedes the disease. (3) It is an abnormal persistence of the fetal, infantile, and child-type of chest. (4) Any chest more than eighteen years of age which shows an index of 80 or higher should be regarded as abnormal and as rendering its possessor more than usually liable to tuberculosis. (5) The occurrence of such a chest in any patient over eighteen years of age, suspected of tuberculosis, raises a strong probability of the disease. (6) The chests of growing boys and girls should be systematically measured at stated intervals, and wherever the index is found distinctly higher than that normal for their age active measures should be taken to remedy the defect. (7) All those sports and exercises which involve wide-swinging use and play of the arm, chest, shoulder group of muscles, such as tree climbing, swinging from ladders, from rings, from bars, ball throwing, spear hurling, tennis, swimming, will tend to correct this defect and flatten the chest down to its proper index.

Shock Produced by General Anæsthesia.—F. B. Turck discusses this question with relation to disturbances of the blood and gastroenteric tract As a result of his experimental studies, he offers the following conclusions: (1) The circulatory disturbance is a direct result of the chloroform or ether acting on the vasomotor centers. (2) The prolonged effect of chloroform and ether on the splanchnic circulation results in congestion associated with fall in temperature. Temperature may fall without fall in blood pressure. (3) The direct effect of the toxins of chloroform and ether acting on cells, with disturbance of metabolism, may produce toxic products. (4) The resulting elaboration of toxins produces symptoms of "autointoxication," associated with the formation of hæmolytic and agglutinating bodies, and precipitins. (5) Indirect toxic effects result from retention of toxic products through disturbances of elimination. (6) There is lessened resistance of the blood serum to normal excreted toxins. (7) There is lessened resistance of the blood serum to bacterial toxins. (8) There is diminished resistance to the development of saprophytic and pathogenic microorganisms. (9) This may be partly explained by the changes observed in the sera, such as diminished antiferment properties, hæmolysis, agglutination, precipitins, etc. (10) That reflex effects result, such as reflex irritation set up by the excretion of the anæsthetic into the stomach and intestines. (11) As the result of atony there is the formation of toxins in the stomach and intestines through bacterial growth. (12) Atony of the stomach and intestines results in the accumulation of gases and interference with the circulation. (13) There is increased toxicity of the stomach contents in the presence of chloroform and ether.

A New Method of Shortening the Round Ligaments Intraperitoneally for Retroversion.—H. T. Byford alludes to the familiar Alexander operation and the modifications thereof made by various colleagues. He advocates another modification, which consists in folding the ligaments anteriorly according to the method of Dudley, but in stitching the loop to the abdominal parietes about opposite or behind and a trifle above the internal inguinal ring. The ligament is grasped with hæmostatic forceps and pulled out of the abdominal incision until it is drawn as far out of the inguinal ring as possible without doing violence to the tissues. Then a medium-sized catgut suture is passed through the center of the ligament about a quarter of an inch from the uterine end, and the same suture is passed through the ligament about half an inch from the internal-inguinal ring. The suture is then drawn tight and tied like an ordinary ligature, except that it, of course, includes only half of the ligament in its grasp. The inner edges of the loop thus formed should now be touched with a chemical irritant, such as Monsel's solution or 1 to 5,000 mercuric bichloride, in order to destroy the endothelium and secure firm adhesions. The irritant is then wiped off and the edges sewed together by fine catgut that entirely closes in and covers up the irritated peritoneal surfaces The end of this fold is then touched with the chemical irritant and stitched forward beside the bladder about opposite and a little above the level of the external inguinal ring. This, of course, will be only a peritoneal attachment and should be rather high, because the peritoneum is held in place here rather loosely. Thus we practically have two round ligaments on either side, one going from the uterus partly through the first catgut ligature to the attachment behind the external inguinal ring, and the other from the uterus to the ligature and from there to the internal inguinal ring, etc.

Philadelphia Medical Journal, May 2, 1903.

The Radical Cure of Inguinal Hernia in Infants and Young Children.—Charles Greene Cumston believes that: (1) Experience has demonstrated the innocuity of radical operation for hernia in infants. (2) The operation is indicated in all cases of strangulation, in all cases in which the contents of the sac cannot be retained by a truss, and in every case in which irritation of the skin is produced by the mechanical appliance, and in children of the poor who cannot receive the necessary and proper attention at their homes.

Report of a Case of Painless Amputation of the Leg after the Intraneural Injection of Cocaine.—John H. Gibbon reports the case of a man of fifty years with a far advanced tuberculous disease of the ankle-joint and bones of the tarsus. Fifteen minutes before the operation, $\frac{1}{4}$ gr morphine and $\frac{1}{150}$ gr. atropine were given hypodermically. The sciatic and anterior crural nerves were then exposed by infiltration anæsthesia (Schleich's fluid), and injected with a 1 per cent cocaine solution. The introduction of the fluid into the nerve was not painful, probably because of the solution already injected about it. It was about eight minutes before anæsthesia was completed. When the circular division of all the soft parts was made, the patient felt no pain. During the amputation and after it there was no evidence of shock except a slightly increased pulse-rate. The temperature immediately after operation was 99.2-5°, pulse 112, respiration 20. The recovery was uneventful. The solution must be pure and fresh, and the technique perfect in order to obtain good results. This method should be limited at this time to cases in which general anæsthesia is contraindicated.

A Case of Perforated Ulcer in Typhoid Fever.—James C. Wilson and George G. Ross emphasize the following points: (1) Eighteen or twenty hours prior to the probable time of perforation the patient became extremely nervous and restless and perspired very freely. Could this have been evidence of threatening perforation? Could the deep ulceration of the bowel wall, until it approached the peritoneal coat, have caused sufficient vasomotor disturbance to account for the vasomotor symptoms? (2) Perforation in which the initial pain was referred to the penis and there persisted for twelve hours without being referred to the abdomen. Could this pain in the penis be due to the proximity of the inflammatory area to the ureter or bladder? (3) Perforation without collapse. This man's temperature remained high, he had no syncope. No vomiting, sweating, or pain in the abdomen. (4) The unavoidable delay in making a positive diagnosis. (5) The difficulty in securing the family's consent and the loss of five hours of valuable time consequent thereto. It has been noticed in many cases that there has been an absence of explosive symptoms, indicating the serious intra-abdominal condition in perforation, and it is probably due to the depressed condition or inactivity of the patient's mental and nervous system.

Medical News, May 2, 1903.

Some Practical Points in the Anatomy of the Gall-bladder Region.—George Emerson Brewer calls attention to the following important points in the anatomy of this region: (1) A knowledge of the position of the nerve trunks of the abdominal wall; (2) a knowledge of the normal position, size, shape, and relations of the gall-bladder and ducts, their blood supply, and the normal position of certain constant lymphatic nodes; (3) the most frequent variations from the normal in these structures, both congenital and acquired; (4) variations in the arrangement of the blood supply of the liver and gall-bladder; (5) the relations of the duodenal orifice of the common bile duct; (6) the anatomy of the infrahepatic peritoneal basin.

The Mortality in Appendicitis; Its Cause and Limitation.

—A. J. Ochsner presents his conclusions on this subject, some of which are as follows: The mortality in appendicitis results from the extension of infection from the appendix, to the peritoneum or from metastatic infection from the same source. This extension can be prevented by removing the appendix while the infectious material is still confined to this organ. Peristaltic action of the small intestines distributes the infection. This is also accomplished by operation after the infectious material has extended beyond the appendix, before it has become circumscribed. In case neither food nor carthartics are given from the beginning of the attack of acute appendicitis and gastric lavage is employed, the mortality is reduced to an extremely low percentage. Even though this treatment has not been employed, and the patient has a beginning diffuse peritonitis, the mortality will still be less than 4 per cent. if peristalsis is inhibited by gastric lavage and the absolute prohibition of all forms of nourishment and carthartics by mouth is established. The mortality following operations for chronic appendicitis is exceedingly low.

Indications for Extirpation of the Gall-bladder.—Maurice H. Richardson concludes that certain lesions in themselves demand removal of the gall-bladder whenever possible. Such are new growths and gangrenes. Contracted and inflamed gall-bladders with thickened walls are better treated by cholecystectomy. All gall-bladders which do not permit easy and efficient drainage should be extirpated. Drainage is preferable in the dilated and infected gall-bladder, which is neither gangrenous nor to any great extent changed. Generally, drainage rather than extirpation is demanded in acute cholecystitis with severe constitutional symptoms. When the gall-bladder is dilated, or at least not contracted, and when it is not gangrenous. In chronic cholecystitis with dilatation and thickening of the gall-bladder, especially when a stone is impacted in the cystic duct, extirpation is preferable, unless the stone can be dislodged backward into the gall-bladder. When drainage is quite as advantageous. In simple gallstones, without evidence of infection or changes incompatible with complete restoration of function, simple drainage is indicated. In chronic pancreatitis, drainage through the gall-bladder is indicated. Reopening of the biliary passages may in the future be required.

American Medicine, May 2, 1903.

An Interesting Complication in the Diagnosis of Gallstone.—Guy L. Hunner reports two cases of omental adhesions to old operation wounds situated at some distance from the gall-bladder. In one case the diagnosis of gallstones was only tentative, while in the other a positive diagnosis was made. The true diagnosis in the second case was suggested only during the operation, and this as a result of observations made while operating on the first patient. The presence of a scar showing a previous abdominal operation should put the surgeon on his guard when making a diagnosis of any obscure abdominal condition, no matter how distant the scar from the site of the symptoms. The second patient was seized with attacks of pain in the hepatic region. They were accompanied by rise of temperature, profuse sweating, nausea, and at times severe vomiting. The attacks of pain were generally intermittent. At operation the gall-bladder and ducts were seen to be perfectly normal. But dense adhesions of the omentum were found at the site of the former wound. These were carefully freed, and the patient made an uneventful recovery.

Some Points Pertaining to the Therapeutic Management of the Uræmic State.—Heinrich Stern states that all uræmic manifestations depend upon the condition of the blood, but while this exhibits some characteristics which are, in a measure, common to all types of uræmia, the serum of every variety possesses some distinctive feature. This is dependent upon the different underlying renal condition, and upon the specific material of the infectious disease, in consequence of which uræmia may appear, and the decomposition products of the retained substances. Promotion of sweating is indicated under certain restrictions in every case of acute uræmia. It is especially valuable when employed soon after the onset of the uræmia phenomena. If sweating is kept up by active measures, enteroclysis with a weak sodium chloride solution, or hypodermoclysis with a hypotonic solution of salt, should be performed at certain intervals. The improvement afforded by venesection is probably due to nothing else but the relief of the vasoconstriction in the kidneys or in the central nervous system or in both these places. Subcutaneous or intravenous introduction of a weak solution of sodium chloride dilutes the blood, produces diuresis, and compensates for the blood lost by venesection. The effects may bridge over a critical phase in the uræmic attack. While morphine in small doses is innocuous in uræmia of acute renal disease and chronic parenchymatous nephritis, and may possibly be a factor in effecting subsidence of convulsive symptoms, it is not indicated in uræmia of chronic interstitial nephritis.

Peritonitis in Typhoid Fever without Perforation, with a Report of One Case Caused by the Bacillus Typhosus, and Another Simulating Acute Appendicitis.—J. L. Yates concludes that: (1) Non-perforative peritonitis usually results from an extension of inflammation through the bases of deep intestinal ulcers, but may also arise from the migration of bacteria through an intestinal wall which is relative but slightly abnormal. (2) Meteorism thus predisposes to infection of the peritoneal cavity, and by decreasing the normal peritoneal absorption furnishes a secondary cause for peritonitis. (3) An hæmotogenous origin of peritonitis is possible in typhoid fever. (4) Non-perforative peritonitis is commonly caused by the typhoid bacillus and the resulting inflammation is usually diffuse and often severe. (5) The inception of such a peritonitis is clinically indistinguishable from the so-called signs of perforation, and the symptoms in both are due to peritoneal inflammation. The prognosis is probably equally grave in the two forms. (6) There should be appropriate surgical intervention immediately the peritonitis can be recognized. Enterostomy is indicated when there is meteorism with the peritonitis, or when it affects the prognosis and is intractable to ordinary therapeutics. (7) Thrombi, and among them those composed of agglutinated red blood-corpuscles, may lead to hemorrhages into the wall of the intestine, and the resulting changes favor the transmigration of bacteria into the peritoneal cavity. (8) Infarction of the spleen may have a similar thrombotic causation, but simple splenic infarction is probably not a cause of peritonitis. (9) The specific action upon human blood of an agglutinin generated by the typhoid bacillus can be demonstrated in vitro.

The Lancet, April 25, 1903.

The Drainage of the Knee-joint in Acute Suppurative Arthritis.—H. L. Barnard advises that all really acute cases for suppuration in the knee-joint, say with a temperature ranging from 103° to 104° F., should be treated by anterior and posterior incisions, more especially if they arise from punctured wounds. When the suppuration arises from autoinfection and is subacute, with a temperature of not more than 102°, the author would first make lateral incisions on either side of the patella and wash out the joint thoroughly and drain it. The joint must be treated as though it were an aseptic case, for in autoinfection we have usually to deal with one microorganism only, and that often a mild one. We must, therefore beware lest in casting out one microorganism we admit several others worse than the first. Should this partial drainage fail to bring the temperature down, in a day or two, the posterior pouches should be laid opened and thoroughly drained.

A Case of Dropsy, the Result of Inflammation of the Kidneys, Treated by Laparotomy.—The patient was a woman of thirty-one years and under the care of H. P. Planer. She had been tapped but without relief. On admission to the hospital, under the author's charge, her urine was very albuminous, the body was greatly swollen and in a state of advanced ascites. Convinced that the cause of the dropsy was kidney disease, he decided to remove the fluid by means of laparotomy. The operation was done under chloroform and ether, a solution of tepid salt water containing a little sodium bicarbonate being at the same time introduced into the breasts. This latter procedure secured a good behavior of the heart during the operation. A large amount of fluid escaped through the abdominal incision. From each side of the latter a strip of the expanded peritoneum was removed and the wound sutured. The effects of the operation were at once manifested for the better. The bowels became regular, secretion of urine was increased, and the albumin disappeared. Three weeks after the operation the patient left the hospital feeling completely well. Ascites had completely disappeared, and nine months later her health was excellent. The author adds to the history of the case a few words of advocacy of laparotomy over tapping in cases of excessive ascites.

Infective Endocarditis in Its Clinical Aspects.—In the third Lumleian lecture T. R. Glynn concludes the discussion of the symptoms of infective endocarditis and goes on to speak of complications, diagnosis, and treatment. The various points made are illustrated by histories of cases that have occurred in his own experience or that have been recorded in literature. He notes that there is at times a close resemblance between chronic tuberculous disease of the lungs and chronic forms of infective endocar-

ditis. In both the onset may be insidious and the symptoms similar—namely, anæmia, wasting, debility, slight pyrexia, and pulmonary troubles. Careful physical investigation, with the examination of the blood and sputum, will probably enable a definite opinion to be formed. When pthisis is associated with chronic disease of the valves of the heart—and the disorder more frequently accompanies mitral disease than was formerly believed—the resultant symptoms necessarily conform to the chronic type of infective endocarditis. Fortunately, in such complicated cases examinations of the apices of the lungs and sputum usually furnish reliable indications of the nature of the disease and disclose the origin of the pyrexia. In one of his cases chronic tuberculous disease of the lungs was associated with infective endocarditis. The disease of the valves of the heart was due to streptococcic infection and not to infection by the tubercle bacillus. He notes the absence of any specific in the treatment of the malady, and does not find much encouragement in the results thus far obtained with anti-streptococcus serum.

The Symptoms and Diagnosis of Stone in the Kidney.—In the Hunterian lecture Clement Lucas enumerates the following as the symptoms of stone in the kidneys: pain, frequent micturition, hæmaturia, retraction of the testis, passage of gravel or small calculi on previous occasions, the grating of multiple calculi, total suppression of urine, the results of skiagraphy and family history. Pain may be absent. To be of much aid in diagnosis it must be unilateral. Its character varies greatly. It may be transferred, radiated or reflected to some distant area. It is worse at night, is increased by jolting exercise, and is said to vary with the composition of the calculus. Lucas mentions also the "stamping test," to the results of which he attaches considerable importance. The patient supports himself by resting one hand on some firm object, then is told to flex the thigh on the suspected side as high as possible. The psoas muscle being thus strongly flexed, by its contracted belly presses the kidney forward and outward. Next the patient brings the limb suddenly down, stamping the heel firmly on the ground. The kidney in this way suddenly loses its muscular support and is caught, as it were, unawares, whilst the jar carried through the pelvis and spine is communicated to it. A sudden acute pain is commonly caused by this manœuvre when a calculus is present. In one case in which he employed this test it answered only too well, for the patient was immediately seized with acute renal colic, which necessitated his being put to bed, where he lay for some hours in great agony. It was evident that a stone had been displaced from a calyx and had fallen over the outlet of the pelvis, whence it was removed by operation some days later.

British Medical Journal, April 25, 1903.

The Surgical Treatment of Gastric Ulcer.—C. Mansell Moullin has operated upon fifteen cases with two deaths. In twelve the ulcer was excised or ligatured in various ways. In two, gastro-jejunostomy was performed, as the ulcer could not be dealt with locally; in one the ulcer proved to be in the duodenum and not in the stomach. In four cases the immediate cause for operation was persistent pain and vomiting. These all recovered. In the other eleven, the cause was hæmatemesis, and in six of these transfusion had to be performed on the table or immediately after. Two of these died. They were both *in extremis* at the time of operation.

Case of Chronic Pancreatitis, with an Account of the Post-mortem Examination.—Gilbert Barling reports both the history and necropsy of this case. There was marked enlargement of the pancreas, and at necropsy the main bile ducts were much dilated. The only condition found which might have caused obstruction to the flow of bile, and with it pancreatic juice, into the bowel was the chronic inflammation in the pancreas. As to treatment, prolonged drainage of the gall-bladder will suffice in some cases, but in others further measures are required.

Knock-out Blows.—James Gray Duncanson states that the temple appears to be a particularly vulnerable part of the head. A swinging, short-arm blow on the ear may cause rupture of the membrana tympani, dizziness, and collapse, followed by sickness. Recovery is slow, but may be perfect. Blows on the body must be above the belt. A severe blow about the cardiac region may cause syncope and death. Diaphragmatic blows are not, as a rule, so dangerous to life. Blows over the kidneys are still inadvisedly admitted as fair. Great shock results from them. Johnstone says: "The most dangerous and infinitely painful form of 'knock-out' is that which is accomplished by a left-hand hook on the mark." The "mark" is the size of the palm of the hand, and corresponds with the center of a triangle formed by the ziphi-sternal articulation above, and a line joining the bony ends of the seventh ribs below; behind this lies the pylorus. Blows on the stomach are attended by great shock.

An Address on the Importance of an Early Diagnosis of Cancer of the Stomach, with a View to Radical Treatment, with Remarks on Operative Results, Immediate and Remote.—A. W. Mayo Robson calls attention to the following points: (1) How desirable it is to make an early diagnosis of cancer of the stomach in order that a radical operation may be performed at the earliest possible moment. (2) That it may be needful to perform an exploratory operation in order to complete or confirm the diagnosis. (3) That such an exploration may be done with little or no risk in the early stages of the disease. (4) That even when the disease is more advanced and a tumor perceptible, an exploratory operation is, as a rule, still advisable, in order to carry out radical or palliative treatment. (5) That where the disease is too extensive for any radical operation to be done the palliative operation of gastroenterostomy, which can be done with very small risk, may considerably prolong life, and make the remainder of it much more comfortable and happy. (6) That some cases, thought at the time to be cancer, too extensive for removal, may, after gastroenterostomy, clear up completely and get quite well. (7) That in cases of disease of the cardiac end of the stomach too extensive for removal, the operation of gastrostomy may considerably prolong life and prove of great comfort to the patient by preventing death from starvation. (8) That even where the disease is too extensive either for removal or for a gastroenterostomy being performed with a fair chance of success, the operation of jejunostomy may occasionally prove of service to the patient. (9) That where a radical operation can be performed, the thorough removal of the disease may bring about as much relief to the patient as does the operation for the removal of cancer in the breast, uterus, and other organs of the body, and that in some cases a complete cure may follow.

Münchener medicinishe Wochenschrift, April 14, 1903.

Abnormal Mobility of the Gall-bladder.—Viktor Lieblein reports a case in which the diagnosis of a carcinoma of a floating right kidney was made. The tumor was freely movable in the abdomen, but situated upon the right side. The patient was plainly cachectic, and the condition was of some months' standing. Upon operation the tumor was found to be the gall-bladder, partially filled with stones. The gall-bladder was opened, the stones evacuated, and the wound closed. Recovery followed. The interest in the case attaches to the absence of all liver or biliary symptoms, the false diagnosis, and the marked mobility of the gall-bladder.

A Rare Case of Measles.—Bernhard Machold reports a case of measles in which, fourteen days after the initial eruption, there appeared over the entire body a bluish macular eruption, which lasted for three days, and which was followed by slight desquamation. The origin of the eruption is somewhat obscure, although it is most probable that it is to be regarded as a recurrent attack of the rubeola. It was certainly not due to the action of any drug or other substance ingested, since the diet of the patient had been carefully watched and no medicine had been administered. During its presence there was no rise in temperature or any constitutional symptoms.

Juvenile Tabes and Its Relation to Hereditary Syphilis.—P. Linser reports a case which adds still further evidence to the syphilitic origin of tabes. The patient was a female, thirty-four years of age, and since her fifteenth year had suffered from indefinite tabic symptoms. Shortly after passing twenty-five years of age, she developed immobility of the pupils, paræsthesial, and loss of the patellar reflex. Thus the diagnosis of tabes was definitely established. As a child the patient had suffered with certain cutaneous eruptions and enlargement of the lymphatic glands. The etiology of these eruptions, etc., was made clear when it was ascertained that the patient's father had died from a progressive paralysis resulting from a syphilitic infection.

Berliner klinische Wochenschrift, April 12, 1903.

A Rare Murmur in the Lung.—P. K. Pel reports the case of a phthisical male, thirty-two years of age, in whom, over the entire upper lobe of the right lung, but loudest in the supraspinatous fossa there was heard a loud systolic murmur, which was of a high-pitched musical tone. The author thinks that its origin was both venous and arterial. This might occur in either one of two conditions: (1) A direct union between the pulmonary artery and vein, an arterio-venous anastomosis, or (2) a dilatation of the vein as it came in contact with the artery. It is probable that in this case, the cause of whichever one of these lesions was present, was to be sought in a tuberculous process of the vessel walls.

Society Reports.

AMERICAN MEDICAL ASSOCIATION.

Fifty-fourth Annual Meeting, Held at New Orleans, La., on May 5–9, 1903

By Telegraph to Medical Record.

GENERAL SESSION, FIRST DAY, MAY 5, 1903

The first general session was held in the Tulane Theatre, New Orleans, La. The theatre was well filled when, at 11 A.M., the President, Dr Frank Billings of Chicago, called the meeting to order. After the opening prayer by the Rev. H. G. Davis, the association was welcomed in a speech by his Honor, Paul Capdeville, the Mayor. Hon. Leon Jastremski of Baton Rouge, representing the Governor, welcomed the association on behalf of the State of Louisiana, paying a graceful tribute to the self-denying life of the medical profession. The New Orleans bar was represented by Henry P. Dart, Esq., who called attention to the evident tendency of the day to assume that not a minute of the twenty-four hours belongs to the physician or his family. One great cause of this was thought to be the rapidly increasing demands of the hospitals. No wonder, the speaker said, that the physician was himself fast becoming an object of charity. He was not only allowed, but even expected to give of his time, body, means, and life-blood, morning, noon, and night. The speaker suggested that the medical profession should halt and seriously consider this momentous question, and see if it were not really doing itself a grievous wrong. Dr. J. A. Witherspoon of Nashville, Tenn., the first vice-president, delivered a stirring and witty address in response to the hearty words of welcome of the preceding speakers.

President's Address.—Dr. Frank Billings of Chicago delivered this address, taking for his theme, "Medical Education in the United States." (vide page 721) After comparing medical education in those days, when numerous money-making medical schools were flourishing, with the few well-equipped modern schools, attention was directed to the ever-increasing domain of medical science, and the great demands upon the students' time. The laboratory method of instruction was commended, but it was pointed out that this was enormously expensive, the cost being estimated at $400 or $500 per student. The pressing need for a broad preliminary education was insisted upon, and it was shown that by a proper adaptation of the curriculum to the needs of the prospective medical student, it was possible to secure the requisite education without an inordinate lengthening of the complete course. In a word, the commercial schools must go, and the medical teaching of the future must be done in a few large universities in the great medical centers. The speaker estimated that 2,500 graduates in medicine would fully satisfy the demand, and as this would mean about 10,000 matriculates this number of students could be cared for in from twenty-five to thirty-five medical schools.

Evening Session: Oration on Surgery.—Dr. A. F. Jonas of Omaha was the orator of the evening.

SECTION ON PRACTICE OF MEDICINE.

W. S. Thayer, M.D., of Baltimore, Md., Chairman.

Address of Chairman.—Dr. W. S. Thayer of Baltimore delivered the opening address, "Observations on the Teaching of Clinical Medicine." He compared the curriculum in most of our schools with that which was required in England and France. In Great Britain, for instance, the schools required at least six months' service as a clinical clerk in the medical ward, and a similar time as a dresser in the surgical wards of a hospital. In Paris the student was required to give the entire morning to ward work for two years, one year in the medical and one year in the surgical department. He believed that an equal amount of experience should be required in this country, but it seemed to be impossible for the following reasons: (1) The absence of State or National laws requiring such work; (2) the multiplicity of medical schools and the existence of many such institutions unconnected with hospitals of sufficient size to furnish material for the instruction of the students; and (3) a widespread prejudice existing in many hospitals against the admission of students to the wards and against the use of patients in general for the purpose of instruction.

The problems involved in the study and teaching of clinical medicine differed in no essential from those connected with the teaching and study of physiology, and until we recognized this fact and met it squarely our clinics would remain unproductive and our teachings inadequate.

The Boy Venereal Peril.—Dr. Ferd. C. Valentine of New York, the author of this paper, summed up his advice in the following words: "If you want to be a healthy, strong, successful man; if you want to live a happy life, do not smoke, do not drink alcoholic beverages, do not associate with corrupt people, and do not indulge in any vices. If you have been so unfortunate as to lose your health for any of the above reasons do not take the advice of an advertiser, do not take advertised drugs, but consult your physician.

Continued Fever, neither Malarial nor Typhoid; a Clinical Study.—Dr. T. J. Happel of Trenton, Tenn., read this paper. He said that the physicians in the North, as a rule, contended that every continued fever was either typhoid or malarial, whilst in the South many physicians were sure that they had to deal with a third fever, the mortality of which was so slight that opportunities for post-mortem study had been so far nil. The blood and secretions had been examined microscopically, and chemically with negative results. The blood did not respond to the Widal test, and it did not show the presence of the plasmodium malariæ. In a former paper he had referred to a number of such cases treated by him in the last ten years, all offering favorable opportunities for careful study at the bedside. He then detailed six additional cases that he had treated since July last, making a total of about one hundred cases. He emphasized the points of difference from a clinical standpoint, and added that the bedside study taught plainly one thing and the work in the laboratory another. These cases were not ushered in abruptly by a chill, but they had usually, for a few days, prodromes of malaise, then rigors; sometimes a slight chill, followed by a slight rise in temperature, which did not attain its maximum for from three days to a week. Whilst this fever presented marked remissions for the first week, they were not so decided as in the second week, and were even more marked in the third week, amounting to intermissions with profuse sweatings. The chills, or cold rigors, were sometimes accompanied by aching of one set of muscles, and sometimes of all, resembling in that respect la grippe. After a day or two all pain ceased and the patient complained of nothing. The intermissions varied from one to four in twenty-four hours and could be made more marked by sponging with tepid water in all cases, by aconite and gelsemium in a few, and by the coal-tar derivatives in almost all of them. One of the most marked peculiarities of this fever was the disproportion between the pulse rate and the temperature. The ratio was frequently reversed, the pulse beating between the normal and ninety with a temperature of 103 to 105°, or even higher. The hand applied to the pulse and then to the forehead would lead one to say that the patient was free from fever when the thermometer in the axilla or mouth would reveal a high temperature.

Southern Fevers.—Dr. William Krauss of Memphis, Tenn., read this paper and summed up his remarks as follows: (1) A very sudden hyperpyrexia in midsummer was more apt to be sunstroke than "congestion"; hence quinine should not be given without cause. (2) The malarial leucocyte count was only collateral evidence

of malarial infection, and the count must include all the cells in the spread. (3) The Widal test might lead us into error in a small percentage of cases; the blood culture test was more difficult and had no negative value. (4) A chill or fulminant onset of a typhoid fever was not sufficient evidence of a complicating malaria. (5) A chill or sudden disturbance of a temperature curve during convalescence in typhoid fever was not necessarily malarial. (6) In a malarial infection, the persistance of an irregular sub-continuous fever after thorough cinchonization was not evidence of a typhoid complication or of remaining plasmodia. (7) A positive diagnosis of summer-fall fevers was not always possible. (8) In the hygienic management of summer-fall fevers we should presuppose a double infection, irrespective of symptoms. (9) Some of the summer-fall fevers were typhoid, some malarial, and a few of them were neither one, but the writer was opposed to the belief of an "this-" fever.

A Clinical Observation of Ninety Cases of Typhoid Fever with Four Deaths, with Special Reference to Therapeutic Fasting.—Dr. R. M. Harbin of Rome, Ga., read this paper. The conclusions that he adduced were as follow:—(1) Fasting or a restricted diet were indicated because of pathological conditions. (2) Clinical facts indicated that emaciation occurred independently of the amount of food taken. (3) All severe cases should be subjected to fasting for twenty-four to forty-eight hours to relieve the active symptoms which exhausted the patient more rapidly than the lack of food. (4) After a fast a restricted diet of broth, diluted milk, etc., in definite quantities should be prescribed. (5) Gelatin prevented too rapid emaciation in certain cases and rendered hemorrhage less liable. (6) The cold bath, or the modified cold bath, was more effective during a fast. (7) Peristalsis favored the absorption of toxins, and cathartics should be used only to remove undigested food. (8) The presence of intestinal ulcers should be assumed to exist in every case, and the proper treatment was rest, which was better attained by fasting and a restricted diet, thus preventing hemorrhage and perforation. (9) The presence of diarrhœa and vomiting indicated the adoption of the fasting treatment. (10) Fasting and a restricted diet shortened the course of the disease, and many cases ran an abortive course after the amphibolic period. (11) Many of the vaunted cures from specific drugs were, in fact, dietetic cures. (12) Recrudescences were nearly always due to dietetic errors. (13) In the report presented there were forty-eight cases without a death. Of eighty-seven whites two, or 2.2 per cent. died; of the colored, two died. The low mortality of 4.4 per cent. of all cases he ascribed to the therapeutic fasting.

A Report of 529 Cases of Typhoid Fever in Colorado.—Dr. J. N. Hall and Dr. C. E. Cooper of Denver, Col., presented this paper. From an analysis of a considerable number of cases covering twenty years in different parts of Colorado, they concluded that typhoid fever was practically the same disease there as elsewhere. Many of the cases called mountain fever had been included in the series presented; they knew of no such disease as "Mountain Fever." Typical examples had hermorrhages, rose spots, Widal reaction, and many of the complications of typhoid, and were certainly typhoid fever. The false name was gradually passing out of use. In 1889 Dr. Hall concluded that, from an analysis from his 108 cases, typhoid fever was milder there than in the East; but a wider experience had convinced him that it did not differ materially in this nor in any other respect from the disease as reported from this or most other countries. He believed that diarrhœa was less frequent in Colorado than elsewhere.

Dr. T. B. Futcher of Baltimore advocated the frequent examination of the blood serum for the Widal test. This was the routine at the Johns Hopkins Hospital, and every case was submitted to such an examination when he was discharged from the hospital. The possibility of a paratyphoid infection should be borne in mind. With reference to the administration of the coal-tar derivatives he said we should remember the fact that they frequently gave rise to chills and sweatings of a rather severe grade. Chills and sweating in typhoid fever might occur at the onset, with the advent of complications, and at the time of convalescence and with the giving of coal-tar derivatives.

Dr. James R. Tyson of Philadelphia said that during an experience of thirty years the tendency had been to limit the number of continued fevers. Each winter he ran across several of these anomalous fevers, which at first eluded diagnosis, but invariably turned out to be either typhoid fever, malaria, or some of the more unusual modifications of typhoid fever, such as paratyphoid or colon-bacillus infection. On the other hand, there was no doubt but that a number of these continued fevers were due to irritative causes, such as intestinal indigestion or the so-called ptomain poisoning, where the irritation would be kept up for a certain length of time.

Dr. J. A. Witherspoon of Nashville, Tenn., had seen several cases such as those described by Dr. Happel, but they had started suddenly, and not gradually. The disease did not occur at the same season as typhoid fever, it might occur at any time from the cradle to the grave. One attack made another more liable to occur, and he had seen five attacks occurring in the same individual. The pulse was rather rapid, prostration was early, and the sweating marked. There was an irregular type of fever, and this was the most noticeable feature. The fever often resembled the septic type. The abdomen was not tympanitic, but rather flat or scaphoid. Constipation was more often present with the passage of scybalous masses. There was not a condition of hebetude, but rather that of irritability. Epistaxis was rare, while herpes labialis was common.

SECTION ON SURGERY AND ANATOMY.

James E. Moore, M.D., Minneapolis, Chairman.

Chairman's Address.—Dr. James E. Moore of Minneapolis opened the meeting of this section with an eloquent plea for exploratory operations. He spoke first of the importance of the surgical laboratories of the day, and dwelt particularly on the great Rockefeller institute of New York. Those institutions, combined with other modern methods of teaching surgery, were producing a young race of men who were competent to do exploratory work. Such men must be highly moral, as well as intellectual, for there was no greater responsibility than that which hinged upon the opening of the human body. The paramount importance of the surgical developments in the upper zone of the abdomen, which had but recently yielded to the efforts of the externist were then referred to The relation of gastric ulcer to carcinoma of the stomach was considered by some authorities to be so close that all of these malignant growths found their origin in the primary ulcer. If this were true, how important must be the early diagnosis obtainable only by exploration. In conclusion, he said that it was impossible to portray the importance, as well as the danger of exploration; all in all, it depended on the moral and on the technique of the operator.

Suppression of Urine.—Dr. H. J. Whitacre of Cincinnati presented this report of a most interesting case:

A young woman had induced abortion upon herself by taking large quantities of ergot, and by introducing a catheter into the uterus. Five days afterward, in addition to having a terrific hemorrhage, she had a temperature of almost 105°. For two days she had passed but four ounces of urine, and it was of the type obtained in hemorrhagic nephritis, except for the absence of casts. After applying all the usual therapeutic agents, including intravenous injection, he resolved

to decorticate the kidneys. Immediately after this operation, improvement was marked, and one hour later the patient began to void urine, improvement from this time was constant and eventful. The author divided suppression of urine into two classes, *i.e.* obstructive and non-obstructive. The treatment of the first was always surgical; that of the second might be.

Fat Necrosis of the Kidney.—Dr. J. R. Guthrie of Iowa read this paper. He said that the formation of fat was not as yet understood physiologically, much less pathologically. Bacteria might be concerned in the change. The cause of the fat necrosis was, however, always associated with certain well-known phenomena, viz., changes in the blood supply, diminished oxygen, narrowing of the arteries, persistent venous congestion. When considering the problem of fat necrosis in the kidney it was not without import to note that these conditions might all be produced by prolapses. A case was cited in which he had been obliged to perform nephrectomy, there seemed little doubt that the destruction of the organ in this case, which amounted to entire liquefaction, was attributable to the prolapse.

The Surgical Treatment of Nephritis.—Dr. A. H. Ferguson of Chicago, in presenting this communication, said that he was sorry to begin by disputing the priority of Edebohls to this operation. He had operated prior to that New York surgeon, and had published his results over a month before him. The cases were both of interstitial nephritis, and in each case the diagnosis was confirmed microscopically by Klebs.

Dr. Arthur Bevan of Chicago opened the discussion of these papers. He said that the importance of the problems associated with anuria had not been given thought by the profession. He would classify anuria as follows: (1) that due to obstruction; (2) that which was of reflex origin, and (3) nephritic anuria. The first was surgical; the second rarely so. He was not slow to denounce decortication, and believed that the important element in the treatment consisted in a wide-reaching nephrotomy.

Dr. Jepson of Iowa agreed that Dr. Edebohls was not the originator of the decapsulation method. He felt that it could be of benefit only in cases of interstitial nephritis.

Dr. McClaren of Minnesota believed that the advantages obtainable by operation in cases of nephralgia were dependent upon the splitting and the stripping of the capsule.

Dr. Gibbons of Scranton said that Edebohls unquestionably was the first to recommend decortication for the treatment of chronic Bright's, and he very emphatically considered it curative.

Dr. Ramón Guitéras of New York said that this operation for chronic Bright's disease was still in its infancy. Recent reports showed that there was no increase in the blood supply after decortication.

Dr. McArthur of Chicago reported a case in which he had decorticated both kidneys with marked improvement.

Dr. Whitaker said that he could not agree with Dr. Bevan's classification, and that relief would come from nephrotomy because of the character of the blood supply from the capsule.

Dr. Ferguson, in closing, said that it was idle to preach as Johnson had done, that in the decorticated kidneys of normal dogs there was no increase in the blood supply, first, because the fatty capsule had not been sufficiently removed, and, second, because these normal and healthy organs did not require such increase.

Indications for Cholecystostomy.—Dr. B. B. Davis of Omaha read this paper. He said that the results of simple drainage of the gall-bladder were often painfully poor. In 20 per cent. the relief was only partial. Fistulæ persisted in about 25 per cent. On the other hand, less than 1 per cent. of these cases in which the bladder had been entirely removed continued to have pain, and fistulæ formation was almost unknown. There were numerous advantages of the more radical operation, and it should always be undertaken whenever the patient's condition warranted it, even in cases of profoundly septic bladders. The function of the gall-bladder was probably as negative as that of the appendix; furthermore, the wall was almost invariably thick, and one of the chief causes of pain was the adhesions which were dragged upon by the peristaltic action of the duodenum. Another advantage of total extirpation was that absolute immunity from gallstones was obtained because the cholesterin, from which the bulk of them was made, formed only from the mucous membrane of the gall-bladder.

Exploratory Operations on the Gall-bladder.—Dr. F. A. Dunsmoor of Minneapolis related a large series of cases, from which it was easy to conclude that a dangerously large number of grave and complicated lesions of the biliary passages presented little or no clinical evidence of their presence. Many of these have no jaundice; they complained simply of dyspepsia. Under the strict limitations which were recognized by all, he urged that exploratory incisions be made with greater freedom and frequency in the upper abdominal regions. When the time came for this to be done there would be fewer deaths from pronounced sepsis of the parts.

Dr. Mays of Minnesota, in the discussion following these papers, said that he was coming to the conclusion that a great deal of care should be exercised in deciding whether to drain a gall-bladder or to cut it out. It was not possible, always, to determine which course was better to pursue at the operation, but a knowledge of the cause of death was helpful. Death ensued mostly in those cases in which the cystic duct had been patent, and was suddenly put out of use by being tied off. This, of course, was not taking into consideration the cases of fulminating sepsis of the gall-bladder. It was fortunate that the majority of the cases in which cholecystostomy was indicated were best suited anatomically, as well as clinically, to this form of operation. Death occurred from acute suppression of the hepatic functions, and he felt that whenever a bladder was cut out, in which the cystic duct had been sufficiently free to allow of its filling with bile, that a drainage tube should always be placed in the severed duct and brought to the surface, so that there should be no possibility of a backward pressure of the bile.

Dr. A. J. Ochsner of Chicago deplored the frequency with which cases of cholelithiasis wandered around vainly looking for relief. Often gastritis was the only symptom, the classic symptoms being frequently absent. He would favor cholecystectomy in every case, but regarded it, except under chosen conditions, as more dangerous to the patient.

Dr. Davis, in closing, said that he did not mean to assert that all cases should be treated by ablation; however, nine-tenths of all gall-bladders which come to operation presented lesions not alone internally, but externally, and in their walls as well. They were friable, bound down by adhesions and functionless. These cases called for removal.

Section on Obstetrics and Diseases of Women.

A. Palmer Dudley of New York, Chairman.

President's Address.—Dr. A. Palmer Dudley said that twenty years ago conservative gynecology was looked upon as more or less foolish; and that followers of the same were considered fit subjects for the insane asylum. The success of operations depended upon the amount of the organs removed. Electricity, for a time, had its innings, but was found to be inadequate for this sort of work. Neurologists called a halt because of the production of premature menopause. In 1887 the author started his

experiments upon the female appendages to see what results might be obtained by conservative operations. He claimed no priority in this sort of work, as in 1885 Carl Schroeder had first done conservative surgery on the female appendages. In 1891 Polk of New York had championed the cause of conservatism in a paper read before the American Medical Association in Washington, D. C. He had tried conservative surgery in 269 cases. His object being to preserve all that portion of the organs which he thought might functionate. The factors which he took into consideration before operating upon a case were age, social position, occupation, and marital condition. In operating upon a female patient for pyosalpinx, if the tube were patent at the uterine end, he opened the tube, washed it out, and dropped it back into the pelvis. Dermoid cysts required radical treatment, and under no consideration, except, perhaps, that the patient or the patient's husband was very desirous of the mother's producing a child, should any portion of the organs be left. Cases of pyosalpinx of recent standing should be entirely excised. In over 10 per cent. of the author's cases in which conservative operation had been done, live children had been born to the mother. Old cases had been followed by extreme neurasthenia and other nervous manifestations of premature menopause.

Appendicitis from the Standpoint of the Gyneocologist.—Dr. H. P. Newman of Chicago read this paper. He said that diagnosis in general was not difficult in cases of appendicitis, but there came cases at times which required more than ordinary skill to determine whether or not the appendix or the tube was involved. Formerly we were content to call the severe cases of appendicitis either typhlitis or perytyphlitis, and the less severe cases were called congestion of the bowels, or gastric fever. Today this condition was more likely to be confounded with pelvic troubles. Peritonitis, from appendical troubles, was always fatal, while peritonitis from tubal disease was less likely to cause death; indeed, the majority of them recovered, as the contents of the tube were usually sterile. The abdomen should be examined most carefully when an operation was performed for any sort of pelvic disease. The appendix should always be looked into, in order that any diseased condition of the same might be discovered during an operation on the pelvic organs. The removal of the appendix depended entirely upon the judgment of the operator. If there were a catarrhal condition present, or if there were any adhesions with it to the adjoining organs, or if it contained concretions, the appendix should be removed. Any localized peritonitis might cause intestinal obstruction. All healthy appendices should be removed if they were in any way adherent to the pelvic organs. Pus tubes and infected cystic tumors should be removed early. The invaginating operation was the one of choice.

Dr. E. Reynolds of Boston said that he was familiar with such cases as the author mentioned, in which the symptoms were not justified by the examination. Action should be controlled by the degree of the symptoms. He thought that moderate tenderness on the right side, with flatus and mucus in the dejecta, assured the diagnosis of chronic condition of the appendages. The appendix was more freely removed than formerly, and in the future would be still more frequently removed.

Dr. E. Ricketts of Cincinnati said appendicitis was not easy to differentiate in all these cases. In cases in which the appendage was attached to the tube and ovary the attacks were not necessarily due to appendicitis.

Dr. Michinard of New Orleans said that appendicitis was only interesting to the gynecologist when the diagnosis lay between appendicitis and salpingitis, and that the operative side of the case of no moment to him. Surgical treatment depended on the diagnosis alone. In chronic appendicitis there was great intensity of the pain in the abdominal wall, whereas in salpingitis the pain lay in the right vaginal fornix, and the same was true of the tumor formation.

Dr. J. H. Carstens of Detroit said if appendicitis were present the uterus was movable it was rare to get pain over McBurney's point in salpingitis, the pain was lower in the latter disease.

Dr. J. Westley Bovee of Washington, D.C., said that no man could expect the appendix to be chased all over the body by McBurney's point. He made it a rule to remove the appendix when the patient's condition warranted it.

Dr. G. Betton Massey of Philadelphia thought that the condition in the author's cases might have been cured by medical treatment; when he had such cases he treated the colon. Dr. Newman, in closing the discussion, said that his purpose was to make the gynecologist more alert in his work, because of the bad results which had followed the leaving in diseased appendices in times gone by. The removal must be left to the best judgment of the surgeon.

Gastric Ulcer—Some Clinical Pathological and Surgical Phases of Gastric Ulcer.—Dr. A. H. Cordier of Kansas City read this paper. He said that if an ulcer existed in the stomach the latter should be put at rest. In all other organs and members in which disease existed the primary treatment was rest. Chronic ulcers were usually found along the lesser curvature and on the posterior wall of the stomach, and were usually oval Healing might produce constriction. Hemorrhages were frequently the cause of death. As the ulcer formed adhesions, the organ to which it was most likely to adhere, because of its relations, was the pancreas. Such a condition might lead to the diagnosis of cancer. Adhesions to the liver might produce dilatation of the stomach. Ulcers did not always perforate into blood vessels, the agglutination to the other organs was a wise provision on the part of nature to forestall any such possibility. The most frequent site of ulcers was found to be in the anterior wall, because these cases most often came to autopsy, while posterior ulcers might perforate and not cause death, because of their adhesions to the other organs. In young girls, during menstruation, pain, tenderness, and vomiting were more frequent. Vomiting was not always accompanied by nausea, and was without effort, occurring fifteen minutes after eating. When the ulcer was near the pylorus, the stomach was more likely to be dilated. Ten per cent. of all gastric cancers had their origin in benign ulcers. Medical treatment of these cases was satisfactory in about 50 per cent. of the cases, but it was most often difficult to get the patient to follow out the line of treatment set out for him. If medical treatment failed, excision was the most satisfactory procedure; personally, he believed the most satisfactory operation was gastroenterostomy. By this operation the mobility of the stomach was limited and the ulcer thus got a chance to heal by rest.

Dr. Carstens of Detroit said that cases of pelvic obstruction from any cause could be more satisfactorily operated upon and cured. He did not believe in the use of the Murphy button, but preferred the McGraw rubber ligature.

Dr. J. G. Clark of Philadelphia said there were two questions involved in such cases: First, how long should the case be treated medically, and, secondly, how and where to find the ulcer. If the ulcers were posterior we could easily find that out by an exploratory gastrostomy. Having located the ulcer, one should operate through the stomach wound and sew up the ulcer from within the stomach.

Dr. Cordier said, in conclusion, that it was not advisable to operate during an alarming hemorrhage. The thing to do was to operate by any method which would insure rapidity. His operation was done mainly that the stomach might be drained of the food which was put into it, and that this food might not be allowed to remain in the stomach and putrify.

GENERAL SESSION, SECOND DAY, MAY 6.

Oration on Medicine.—By Dr. J. M. Anders of Philadelphia (see page 726).

SECTION ON OBSTETRICS.

Infected Gall-bladder Contents, with or without Gall-stones.—Dr. Edwin Ricketts of Cincinnati read this paper. He said that gallstones must be considered a disease *per se*. A healthy gall-bladder should touch the neighboring organs and have tonicity. Cholecystostomy was the best operation until one was satisfied that there was free drainage through the gall duct. The gall-bladder could be infected without the involvement of the duct, which would be patent, and still the patient would die. Jaundice was a serious complication, because the bile was much more poisonous than urine. In infected gall-bladders it was well to make the incision over the gall-bladder, and to make an effort to shove the stone down through the duct.

Dr. S. H. Dunning of Indianapolis said that it was important to know when to operate, and how much should be done when infection was associated with stone.

Dr. Thompson of Scranton said he never found it to be necessary to open the duodenum to dislodge a stone in the common duct.

Dr. H. O. Marcy of Boston said the whole question was to know how and when to make a diagnosis.

Dr. Ricketts, in closing, said it was the emergency that bothered us. There was never that case of stone in the duct that the doctor should not have recognized it from symptoms, long before it was necessary for the surgeon to operate.

The Better Methods for the Repair of Perineal Structures.—Dr. H. O. Marcy of Boston read this paper. He reviewed the many methods which had been in vogue for some time past, and then gave the technic of an operation which he had been employing for some years past. The chief point about his operation was that most of the sutures were buried, and thus overcame some of the possibility of subsequent infection. The use of buried animal sutures was advocated by the doctor.

Dr. A. H. Goelet of New York said that the deep suture constricted the parts and shut off the circulation, and as a result failure often followed this method of operation.

Dr. R. H. Gibbons of Scranton said that Dr. Marcy's stitch was fully adequate; personally, he always did Emmet's operation.

Dr. Marcy said, in closing, that the transverse muscles and the levator were evidently the important points of the operation. The repair of cystocele by utilization of the anatomic attachments of the anterior vaginal wall.

Dr. E. Reynolds of Boston read this paper. He said that this condition should be treated as a hernia in any other place. At the conclusion of labor, the anterior wall of the vagina was distended, but its edges persisted where they were. The author's operation was especially excellent when there was a prolapse of the cervix. It freed the traction on the cervix in the median line. The vagina was freed from the cervix, which permitted the cervix to return to its proper position. Dr. Marcy thought that we should congratulate Dr. Reynolds because of this excellent new operation.

Dr. J. Wesley Bovee of Washington, D. C., thought that this operation would draw the uterus forward.

Dr. Reynolds, in closing, said that, curiously enough, there was a transverse narrowing of the vaginal wall and elongation of the anterior wall.

Lacerations of the Cervix: When Shall They Be Repaired.—Dr. D. H. Craig of Boston read this paper, and said that he had undertaken his investigations to learn: first, if plastic repair was curative; second, if the cervix was relacerated in subsequent labors; third, if plastic repairs would guard against subsequent cancer of the cervix. The doctor had followed his cases up most carefully for over two years, and thought that in no instance had any of these cases been followed by cancer of the cervix; that a larger majority of the cases had been cured of their ailments; that a greater proportion of those which had not been cured were benefited a great deal, and that none was worse than before the operation. He thought that the operation should be performed just as soon as the condition produced symptoms which gave any trouble or discomfort.

Dr. G. Betton Massey of Philadelphia had seen a great many failures, which were of two characters: first, failure to remove the nervous symptom; second, those due to lack of medical treatment before the operation.

Dr. Bacon of Chicago said that repair was important under all conditions when the tear extended up into the musculature of the uterus.

Dr. Craig, in closing, said that he believed it best to remove the diseased tissue with a knife, and not with scissors, which left behind some of the diseased tissue.

The Hygiene of Young Girls.—Dr. J. H. Carstens of Detroit read this paper, and remarked that the majority of pelvic diseases in young women, and those of an older age, were due to a lack of the proper training of the child at the time when she was entering in upon the genital of functions adult life. He believed that the mother of a child was usually responsible for the poor condition which resulted from improper teaching and coaching in the simplest laws of hygiene and cleanliness. He wished to impress upon the members of the association that it was their duty to teach the mothers how properly to instruct their daughters at the period when menstruation began.

Pelvic Disease in Young Girls.—Dr. F. Lawrence of Columbus, Ohio, read this paper. The important point in the treatment of pelvic disease in young girls was, he said, to make a proper examination of the patient and to know definitely what condition was to confront the doctor. Too much modesty had been the rule in this condition, and he thought it was time to call a halt. The treatment of the trouble itself differed in no way from the same conditions in the adult woman.

Dr. McMurtrie of St. Louis, in discussing this paper, remarked that there was much to be done in prohibiting others from doing things for these patients. Their treatment began and belonged with the family doctor.

Dr. G. Betton Massey said that the mal developments were due to the carelessness of the mother. That too much stress could not be laid upon the subject of proper clothing.

Dr. Cardtens, in closing, said that it was best to let the young girls alone: "Let us have less medicine, less speculum."

Dr. Lawrence, in closing the discussion on his paper, said that the gynecologist should never be hampered or prevented from making a proper examination.

Fixation of the Prolapsed Kidney.—Dr. A. H. Goilet of New York read this paper, and remarked that fixation of the prolapsed kidney was absolutely a surgical procedure. Belts and corsets were inadequate if the kidney has descended below the border of the ribs. When the colon became distended it dragged the kidney down. Belts were good before this descent had taken place, but afterward they might irritate the prolapsed kidney. The indications for operation were, first of all, when the kidney should have descended below the border of the ribs, and in which the patient was nervous or hysterical. He described a new operation whereby the kidney could be drawn up under the border of the ribs and held there until adhesion had taken place. In a great many of the cases he used gauze for drainage, but did not think that this was absolutely essential for the cure of the disease.

A Combined Clinical and Laboratory Study of the Effects of Peritoneal Saline Infusions in Abdominal Operation.—Dr. J. G. Clark of Philadelphia read this paper. From laboratory methods he had found that the introduction

of large quantities of salt-solution into the abdominal cavity after operations, lessened in a very marked degree the mortality in these cases. When bacteria had been injected into the abdominal cavity without salt-solution, death had resulted in every one of his experimental cases within twenty-four hours. He had used a bouillon culture of staphylococcus aureus.

Retroversion of the Uterus: A Clinical Study of the Symptoms, Complications, and Treatment.—Dr. L. H. Dunning of Indianapolis read this paper. In general, he said the chief difficulty in this condition was the fact that operators did not give their patients sufficient medical treatment before they resorted to operative methods. A further report on operations on the utero sacral and round ligaments for retroversion of the uterus.

Dr. J. Wesley Bovee of Washington, D. C., read this paper, in which he reported forty-one additional cases, which were complicated in many ways, but which had been operated upon by him with the Webster-Baldy operation.

Dr. G. Betton Massey said he preferred to treat these cases by electricity, provided there was no ovarian disease. He had treated them when there was ovarian complication by means of cataphoresis with mercury and electricity.

Dr. Carstens said that all operations upon retroversion might be good in some *selected* cases.

SECTION ON PRACTICE OF MEDICINE.

Weakness and Dilatation of the Heart Due to Chronic Nutritional Diseases.—Dr. G. W. McCaskey of Fort Wayne Ind., read this paper. He said that the various causes which acted upon the heart did so in the following ways: (1) A failure to supply sufficient nutritive pabulum to the heart muscles, because of a weakening of the complicated mechanism concerned in this accomplishment. (2) Through the chemical influence of retention products which were toxic in excess, and the absorption of foreign substances for the most part in the gastrointestinal tract. (3) Through the partial failure or perversion of the important phenomenon of innervation of the heart muscle. (4) The purely mechanic factor which was operative from the moment when the cardiac muscle was unable to make an effective ventricular contraction against the resistance offered in the arteries. Slighter grades of dilatation were frequent in chronic gastrointestinal diseases and in all the severer form of anæmia. The treatment consisted in the removal of the primary disease, improved nutrition, rest, diet, graduated exercise and, in the severer forms, cardiac tonics and saline carbonated baths. In conclusion, he emphasized the favorable prognosis of dilatation of the heart in most cases.

Limitation of Non-surgical Treatment in Intestinal Obstruction.—Dr. Joseph Rilus Eastman of Indianapolis, Ind., read this paper. After a brief consideration of the mechanical obstructions, functional closures, and the cases that were amenable to treatment by non-surgical methods, he took up briefly the consideration of the difficulties in distinguishing the mechanical from the reflex ileus. He cautioned strongly against the use of morphine which so masked the symptoms. He claimed that physicians did not promptly diagnose and advise operations in intestinal obstructions, and, as a rule, the surgeon was called in too late. The earlier and better operating lowered very much the mortality. As a rule the urgency of operation was not so great in obstructions of the large intestine as in closure of the small gut. In the former sedatives, hot stupes, taxis, and enemata might be justly employed for a longer time.

The Occurrence of Stronguloides Intestinalis in the United States.—Dr. M. L. Price of Baltimore read this paper. He presented an account of one of the rarer nematodes, at least rare in this climate and latitude, though occurring frequently in tropical and sub-tropical countries, the stronguloides intestinalis, a parasite endemic in Cochin-China, where it occurred in association with the diarrhœas peculiar to that country, and hence called by European physicians "Cochin diarrhœa."

Clinical Diagnosis of Intestinal Parasites with Blackboard Demonstrations.—Dr. Chas. W. Stiles of Washington, D. C., discussed the various methods of distinguishing infection with intestinal parasites, and particular stress was laid upon the diagnosis of hookworm disease.

Uncinariasis in the United States with Especial Reference to Its Occurrence in Texas.—Dr. Allen J. Smith of Galveston, Tex., read this paper. He made a brief statement of known distribution of the uncinariasis in the United States. He detailed eight cases met in the examinations of eighty-eight persons supposed to be healthy. He gave the gross and minute features of the parasite, with especial reference to the propriety of Stiles' new species uncinariasis Americana. He also made a comparison with the uncinariasis duodenalis and the unci iariasis stenocephala (dog), and the frequent occurrence of the latter in very similar localities.

Treatment of Uncinariasis.—Dr. Thos. A. Clayton of Washington, D. C., read this paper. He considered the means which he adopted to prevent infection with the hookworm, and the destruction of the parasites in those affected. The conclusions he drew from some experimental work done to determine whether or not the alcoholic solution of thymol could be safely used were as follows: (1) The alcoholic solution of thymol was dangerous to dogs even in small doses, chiefly because of its tendency to produce inflammation of the lungs by aspiration. (2) The alcoholic solution, even when rendered bland by the addition of oil, was dangerous in doses of more than 4 grams to dogs of sixteen or seventeen pounds, because of its irritative effect on the gastrointestinal mucous membrane. (3) In dry powder the drug may be given to dogs in large doses without serious results, no depression, no fall of temperature. (4) Gram doses, given hypodermically, cause only local inflammation. (5) There was probably no danger in giving 2 to 4 grams, followed by 1 to 2 tablespoonfuls of brandy, to a human adult, if followed in a few hours by a purgative, such as castor oil or magnesium sulphate. (6) It was probable that the alcoholic solution obtained in this way would be more effective against the parasites, as seemed proven by their much earlier appearance in the stools after the use of alcoholic solution.

Tropical Dysentery.—Dr. Chas. F. Mason, U. S. A., read this paper. His plan of treatment, as the result of experience gained in the Southern States, was to give 10 grains of epsom salts in half a glassful of water every hour until a movement was obtained free from blood and mucus. This was combined with irrigation of the lower bowel with warm normal salt-solution two or three times a day. So soon as the movements assumed an ordinary diarrhœal character, he gave astringents in large doses, such as bismuth subgallate, combined, perhaps, with a little Dover's powder, every three or four hours. The lower down in the bowel the lesions were seated the more important became the local treatment by irrigation. In convalescence great care was required in the management of the diet. In the subacute and chronic cases the treatment was somewhat different, but even here salines could be used with advantage in the beginning. The patient should be given an anæsthetic, the sphincter well dilated, and the rectum carefully examined with the speculum to detect ulcers, which should be scraped with a curette or touched with pure carbolic acid or lunar caustic. After this, the use of saline injections two or three times a day, with proper diet, often sufficed to effect a cure. Internally large doses of dermatol were useful in such cases.

A Contribution to the Study of the Summer Diarrhœas of Infancy.—Dr. J. H. Mason Knox of Baltimore, Md., read this paper. He summarized his conclusions as fol-

lows: (1) The diarrhœal disorders of a large series of children treated in the Thomas Wilson Sanitarium during the summer of 1902 was produced by a bacillus thought to be identical with the bacillus dysenteriæ shiga. (2) The cases in this series presented the clinical and patho logical features of the several forms of the summer diarrhœas of infancy. (3) There was good reason for the confidence that a proportion, and probably a large one, of the so-called summer diarrhœas of infancy were caused by the bacillus s iga. (4) A confirmation of the work of Duval and Bassett by establishing the etiology of this yearly epidemic among infants would make possible the use of more intellectual means to control and suppress it. (5) More success could be expected from prophylactic measures and from medicinal and serumtherapy than ever before.

Malarial Dysentery.—Dr. Wm. Britt Burns of Memphis, Tenn., read this paper. He discussed the possibility or even probability of there occurring a dysentery with the malarial parasite as a causative factor. He called attention to finding malarial parasites and pigment in the vessels of the intestinal mucosa and to the almost invariable amenability of these dysentery to quinine therapy.

The Clinical History and Pathology of Amœbic Dysentery.—Dr. H. F. Harris of Atlanta, Ga., read this paper. After considering the macroscopical appearance of the lesions, he related the sequence of events that occurred in the puppy after receiving an injection of material containing living amœbæ.

A Study of the Cases of Amœbic Dysentery Occurring at the Johns Hopkins Hospital.—Dr. T. B. Futcher of Baltimore, Md., read this paper and gave the following summary: (1) In nearly fourteen years 119 cases of amœbic infection had been admitted to the Johns Hopkins Hospiatl. Of these 118 were cases of amœbic dysentery or its complications, the remaining case being one of amœbic abscess on the floor of the mouth. (2) Of the 119 cases, 117 were admitted to the medical wards. During this time there were 15,817 medical admissions, the cases of amœbic dysentery consisting of 0.73 per cent. of the total. (3) Of the 118 cases of amœbic dysentery the infection in 82 was apparently contracted in Baltimore and in 13 in the State of Maryland outside of Baltimore, or a total of 95 cases contracted within the borders of Maryland. (4) The largest number of cases occurred in the third decade, 35 having developed between twenty-one and thirty years of age. The youngest was a child of two years and eight months and the oldest a man of seventy-one. (5) A point of practical interest was the comparatively large number of infections in children under ten years. Eleven cases or 9.4 per cent. occurred in the first decade, 6 of these developing in the first hemi-decade. (6) The disease was much more prevalent in males; the series was composed of 107 males and only 11 females. (7) There were 107 whites and 12 blacks, or a proportion of 9 to 1. The ratio of all admissions for all diseases in the two races being 7 to 1. (8) A secondary anæmia of moderate grade occurred. A striking feature was the polycythæmia in many cases. A moderate leucocytosis existed; that in cases with hepatic abscess being only a trifle higher than that in uncomplicated cases. (9) Hepatic abscess occurred in 24 or 20.3 per cent. of the cases. Eight of these ruptured into the lung producing an hepato-pulmonary abscess. In 15 of these cases that came to autopsy 9 showed a single large abscess in the right lobe and 6 presented multiple abscesses. (10) Perforation of the colon with peritonitis occurred in 3 cases. (11) Intestinal hemorrhage occurred in three cases. (12) Five of the cases were complicated by malaria and one by a strongyloides intestinalis infection and two by typhoid fever. (13) The agglutination blood tests indicated that the disease was not associated with dysentery due to bacillus dysenteriæ shiga. (14) A marked feature of the disease was its tendency to relapse, 19 patients being readmitted one or more times. (15) The mortality was high, 29 or 24.5 per cent. terminating fatally. (16) Quinine irrigations afforded the most satisfactory means of treatment.

The Treatment of Acute Dysentery.—Dr. John M. Anders of Philadelphia read this paper. He said that a proper regimen tended to render the course of the disease milder. The patient should have rest in bed, proper ventilation, proper diet, and attention should be paid to the manner of feeding, the aim being to minimize the intestinal contents and thus the amount of decomposable material that reaches the seat of the morbid changes. Properly carried out milk diet made the least intestinal putrefaction. Albumin water was highly serviceable. Ipecacuanha stood preëminent among special drugs, but it had no specific action. He advised the use of saline laxatives, particularly magnesium sulphate, which produced an eliminative effect and depleted the intestinal mucosa and inhibited undue peristalsis. This might be followed with aromatic sulphuric acid or sulphur with benefit. To render the intestinal contents acid sulphur or sulphuric acid was rational. To meet the pain irritability and undue peristalsis opium was indicated. Preparations of bismuth we e valuable, particularly in advanced stages, and might be advantageously combined with Dover's powder and antiseptics. He advised intestinal irrigations, but believed they were more suited and more efficacious in amœbic dysentery than in the acute bacillary form. In amœbic dysentery warm solutions of quinine were more or less efficacious.

Abdominal Pain in Pleurisy and Pneumonia.—Dr. James B. Herrick of Chicago read this paper and made reference to the pain occasionally seen in the abdomen in pleurisy and pneumonia, which he attempted to explain by the involvement of the lower intercostal nerves and the possible influence of the phrenic nerve. In cases of this abdominal reference to pain certain abdominal diseases, such as appendicitis, cholecystitis, etc., might be simulated. Diagnosis was largely a matter of careful physical examination.

Traumatic Pneumonia.—Dr. W. T English of Pittsburg, Pa., read this paper. He limited his discussion to concussion and contusion without penetrating wounds or fractures, speaking of the normal and abnormal peculiarities favoring or resisting extrinsic or intrinsic stress, with the citation of cases.

SECTION ON SURGERY.

Surgery of Gastric Ulcer.—Dr. Van Buren Knott of Iowa read this paper. He considered in detail the diagnosis, prognosis, and treatment of adhesions between the stomach and neighboring viscera resulting from gastric ulcer. Forty-two and one-half per cent. of all peptic ulcers gave adhesions of greater or less extent, owing to the involvement of the serous surfaces. Eighty per cent. of all adhesions formed between the liver, pancreas, and stomach, because of the frequency of ulceration in the pyloric region. The size of these adhesions varied from a mere thread to bands extensive as the broad ligaments of the pelvis. The symptoms were not as yet recognizable, because little work has been done on these lines, but, in general, they were those of gastric unrest. However, if the adhesions were severe, they might produce symptoms of grave danger to life, though they could scarcely be recognized clinically from those produced by cancer. Pain might be severe, due partly to the mechanical interference of the peristalsis wave and partly to the fact that irritation was produced in the stomach by the pockets resulting from traction. As guides to diagnosis, he mentioned the existence of a fixed point of tenderness, of pronounced pain while in the knee-chest position, of irregular gastric outline, when distended after Mayos' method. Diagnosis, however, was usually impossible except after exploration. The bands, if dense, would be treated with respect, because it

was very difficult to prevent their reformation after extensive tearing. It was better to leave these cases alone, and to sidetrack the stomach by a gastroenterostomy.

Pyloric Obstruction.—Dr. H. D. Niles of Salt Lake City, Utah, read this paper. He said that cancer, ulcer, or inflammatory adhesions produced 95 per cent. of all phloric obstructions. Great good could undoubtedly be done by pyloroplastic operations, if the internist would recognize that the treatment of these cases was entirely outside of his jurisdiction. Unfortunately, the reconstructive powers of the patient were so exhausted that the mortality of the removing operations was so nearly prohibitive that conservative surgery demanded the simpler and safer gastroenterostomy. He spoke of the pathology of the necrotic process, and believed that it was in the stomach, as elsewhere, modified by the presence of pepsin, by traction and occlusion of the blood vessels. In diagnosing these conditions, it was wise to suspect every case of hysteria combined with gastric irritability, to be a possible example of pyloric obstruction. The rational treatment after exclusion was surgical.

Stomach Surgery.—Dr. A. J. Ochsner of Chicago presented this paper. He said that in time the surgery of the stomach would be simply that of gastric ulcer. To-day we were treating the sequelæ and complications of this condition; namely, hemorrhage, perforation, peritonitis, and carcinoma. Mayo had taught us how to dispose of the vicious circle which but a few years ago was so aggravating as to lead to a multitude of ingenious devices directed toward its prevention. Of these, entero-enterostomy was by far the best known. To-day, however, we knew that all were happily useless. There was no occasion whatsoever for the existence of the cycle if only the most dependent portion of the stomach were chosen for the site of the anastomosis. He spoke very favorably of the results obtained from the McGraw elastic ligature, and said that he believed it to be the safest of all known methods. One of its great advantages was that lumen could be made as large as one chose, thus obviating the possibility of a closing of the opening after healing of the ulcer with subsequent reulceration, and a repetition of the symptoms. Gastrectomy must remain always a rare operation, but partial gastrectomy, the technic of which he gave in detail, would be used more and more as the opportunity for early operation becomes greater. H. De Mayo, in opening the discussion, said that surgery has a great problem before it in answering the question of how to treat gastric ulcer, so soon as we found a suitable method for this most frequent and dangerous complaint, the operations which were common to-day, would pass out of existence.

Dr. Rodman of Philadelphia said that we should all remember the importance of gastric ulceration; much work was necessary to determine the proper methods of treating the ulcer, which was a primary step in all gastric surgical complaints. He believed that the better method for treating gastric ulcer was partial gastrectomy, because, unlike the palliative operation of drainage, it removed what might later become the seat of a cancer, a hemorrhage, or a perforation. He was unable to agree with Dr. Mayo that all cases would be free from the vicious circle of vomiting simply by placing the anastomosis at the most dependent part; and believed that in occasionally a subsequent entero-anastomosis would be necessary.

Dr. A. J. Ochsner of Chicago hoped that the future would yield a larger percentage of permanent cures following partial gastrectomy for malignant growths. The chief point in his admirable technic was the closure of the severed ends both of duodenum and of stomach, and the subsequent junction of the remaining stomach bulb, by its most dependent part to the upper jejunum.

Circular Enterorrhaphy.—Dr. O. Beverly Campbell of St. Joseph, Mo., read this paper. He said that the enormous number of methods of making end-to-end anastomosis showed that the ideal technic was yet to be discovered. He described in detail, his own technic, which consisted in turning a cuff of the superficial layers of the gut back, removing the intervening mucous membrane, suturing the parts, covering the sutures with the cuff, and lastly suturing the serous surface of the cuff to that of the gut.

Intestinal Resection.—Dr. James H. Dunn of Minneapolis said that for the man who only occasionally did abdominal surgery it was necessary to have one or two good methods absolutely perfected. The Connell suture, because of its simplicity and strength, should in most cases be employed upon the great gut, whereas the Murphy button, which was by far the best of the many mechanical devices, found its best use in the region of the small intestine.

Dr. Walker of Detroit, in discussing these papers, said that the McGraw ligature had given very good results in his hands.

Dr. J. B. Murphy of Chicago believed that failure to obtain union was, in all cases, due to not recognizing that the juxtaposed serous surfaces were unhealthy.

Multiple Osteomyelitis.—Dr. John T. Bottomley of Boston read this paper. He cited the case of an adult male, aged forty-three years, who presented a remarkable series of streptococcic infections of nearly all of the bones of the extremities. The man when first observed was suffering from a pulmonary abscess, which unquestionably was the foundation supplying the repeated infections. Clinically, he said the streptococcus and staphylococcus types of bone disease did not materially differ, but the first was very rarely seen.

Osteomyelitis.—Dr. Edward H. Nichols of Boston presented this paper, which was based upon the fact that bone was reformed from the medulla or endosteum, as well as from the periosteum. He urged that the marrow which was usually scraped out should be left *in situ*. Inasmuch as the periosteum was usually separated from the shaft, he further advised its entire removal. There were three stages in which to operate: First, the acute suppurative, with septicæmia, calling for immediate operation; secondly, the subacute, requiring the necrotic shaft to be removed about the tenth week; thirdly, those chronic cases in which a dense involucrum had formed possessing no power of repair. The operation should be done the fifth month. If the endosteum were left, sequestrum formation would be prevented.

Dr. DeForest Willard of Philadelphia in opposing the discussion said that too much stress could not be laid upon the need of all practitioners learning to diagnose this disease. It was as fulminating as any case of appendicitis, and should be treated within the first forty-eight hours.

Dr. Stewart of Minnesota said that rheumatism was not the only thing with which it was confounded, typhoid fever might under certain conditions readily be mistaken for it

Dr J. B. Murphy of Chicago said that this could be no excuse for not diagnosing almost every case. The surgeon was of little use unless he operated upon the bone prior to the bursting through of the pus. The most important point in differentiating he believed to be pain on deep and continued pressure. In closing, Dr. Nichols said that he did not agree that the differentiation between acute rheumatism and osteomyelitis was easy, or even possible, because he had seen many children so overcome by the toxæmia as to be insensible to pain.

Treatment of Vascular Tumors by the Injection of Boiling Water.—Dr John A. Wyeth of New York presented this paper. He classified the three types of vascular tumors in their order of election for this form of treatment. He had found the introduction of steam and

boiling water into the tissues superior to that of alcohol or wax, and believed that this method could be advantageously used in the treatment of cervical adenitis, fistula and possibly fibroids. He distinctly stated that it was indicated only in those cases in which extirpation was impossible.

The Radical Cure of Umbilical Hernia.—Dr. W. J. Mayo of Rochester read this paper. He said that the results in thirty-five cases had been most gratifying, only one having relapsed. The fact that there was no mortality in these cases was in itself a great gain over the old operation.

Dr. A. J. Ochsner of Chicago, in opening the discussion, said that the old operation produced ten times the traumatism of that devised by Mayo, and that this operation rendered absolute cure as certain as Bassini's had in the case of inguinal hernia.

Dr. J. B. Murphy of Chicago had nothing but praise to offer for the technic. The mortality of the old operation was due to pulmonary œdema induced by pressure from constriction of the walls.

The Value of Enterostomy in Peritonitis.—Dr F. B. Lund of Boston was the author of this paper. He said in the milder cases of intestinal paresis, due to whatever cause, recourse should certainly be had to the usual methods of correcting the trouble. These failing, however, in a certain proportion of cases iliostotomy, done under cocaine, was occasionally a life-saving method. He reported a number of cases in which it had been used when the patient was moribund, and in which the success had been so great as to justify the conclusion that the symptoms were due more to mechanical pressure than to toxæmia. It had its objections. The fecal fistula might be permanent, and the excoriations of these were painful, but it was better to accept these minor inconveniences than run the chance of the patients perishing by pressure of the gas within him.

Dr. Martin B. Tinker of Baltimore in discussing the technic, said that it had been said that it had been used successfully a number of times at the Johns Hopkins Hospital, and that within the last three years they had not found it necessary to operate upon any fistulæ, as all of them had closed spontaneously.

Tuberculosis	338	181
Typhoid fever	43	16
Cerebrospinal meningitis	.	..

Primary Cancer of Liver in a Girl Aged Twenty-one Years.—W. J. Thompson reports a case which is interesting from the facts of the patient's age, the absence of any family history, the painless character of the affection, and the lateness at which ascites, nodules, and jaundice appeared The disease lasted altogether about seven months, and at four months the liver was uniformly enlarged and smooth on the surface, and free from pain, even on pressure. Six weeks later ascites appeared, and a couple of weeks after this a slight jaundice, and slight nodules. The latter soon became well marked. Before death the liver extended as far down as the umbilicus, and when removed from the body weighed 197 ounces. The death, temperature remained normal until ten days before when it fluctuated very much, sometimes going as high as 103°.—*The Dublin Journal of Medical Science.*

London Traffic.—A royal commission has been appointed to inquire into the means of locomotion and transport in London, and to report: (1) As to the measures which it deems most effectual for the improvement of the same by the development and interconnection of the railways and tramways, on or below the surface, by increasing the facilities for other forms of mechanical locomotion by better provision for the organization and regulation of vehicular and pedestrian traffic or otherwise; and (2) as to the desirability of establishing some authority or tribunal to which all schemes of railway or tramway construction of a local character should be referred, and the powers which it would be advisable to confer upon such a body.

Health Report.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, U. S. Marine Hospital Service during the week ending May 2, 1903:

URÆMIA AND ITS TREATMENT.*

By W. H. THOMSON, M.D., L.L.D.,
NEW YORK.
PHYSICIAN TO ROOSEVELT HOSPITAL.

Correct physiology is always an essential prerequisite to correct pathology; for if we are to know what is abnormal, we must first know what is normal. But, unfortunately, it is this truth which makes it difficult to handle satisfactorily our present subject, for it happens that there are no important organs of the body about the mechanism of whose physiological functions there are so many undetermined questions as in the case of the kidneys.

To begin with, we meet with the strange paradox that the more you experimentally cut away of the substance of the kidneys the more they will excrete. According to Rose Bradford, if you remove two-thirds of both kidneys in dogs, the animals will live quite well, and actually pass more urine and more urea than they did before the operation; but if you remove three-fourths, they are sure to die after a while, apparently because of excessive polyuria and excessive excretion of urea by the remaining fourth, their muscular tissues seeming to break down rapidly and decompose into the elements which go to form urea.

It would seem from this that in the case of the kidneys a small part is greater than the whole.

In explanation of these results of experimental pathology, it has been suggested that in health the glomeruli of the kidneys let enough water pass through to drain off the whole liquid of the serum, but that, as the water trickles through the multitude of little trombones, called Henle's tubes, the fluid becomes concentrated by reabsorption in them. In support of this surmise, the marked polyuria accompanying cirrhosed kidneys, is ascribed to the extensive atrophy of the convoluted tubes diminishing the surface area for reabsorption in such wasted organs.

On the other hand, the breaking down of the proteid tissues throughout the body, with consequent excess of urea excretion when only a fourth part of kidney substance remains, is more difficult of explanation; and the only theory advanced is that the kidneys have an important function in the shape of an internal secretion, which controls and prevents undue waste of the nitrogenous tissues. Such an internal secretion would correspond to that of the islands of Langerhans in the pancreas, whose function is to prevent a saccharine diabetes, while their renal analogues prevent a urea diabetes. On this view, the kidneys both excrete urea, and limit its production. Again, one would suppose that the presence and relative proportions of the inorganic salts of the urine were simpler problems to investigate, than its urea, uric acid and other of its organic ingredients. Accordingly, scores of animals, have been sacrificed to explain why the chlorides disappear from the urine in pneumonia, in typhoid fever, and in other acute fevers. I have read expositions of four different theories based upon elaborate experimental researches to settle this question; but the conclusions of all four are contradictory to, and mutually excluding, the others. And yet the subject itself is one not only of physiological, but of practical interest. Do the kidneys simply filter the salts through, or is it by vital secretion of their cells, and should we, or should we not, give common salt in typhoid fever to compensate for the deficiency? One investigator says that we ought to give salt freely, 30 grams or more a day; another says, no; and another that it would make no difference either way. Meantime, the case is worse yet as regards the sulphates, and still more so with the phosphates.

If, therefore, physiology is here uncertain, then pathology must be uncertain, and derangements of the kidneys must present us with quite a list of riddles. Meantime, as scientific therapeutics should be based on correct pathology, and that in turn on correct physiology, it would seem as if our third superstructure must be still more insecure.

Nevertheless, *clinical* experience does furnish us with certain distinct indications of special conditions in kidney diseases which can be broadly distinguished from each other; and it is about some of those that I propose to speak.

Instances do occur of persons while in good health having the urine suddenly stopped from entering the bladder. This is by what is termed acute obstructive suppression, and the remarkable after-course of these patients, if not relieved, is illustrated by narrating a case which came under my own observation. I was requested by his employer to see, in consultation with his physician, a man who had not passed a drop of urine for eight days. I found the patient, a stout, healthy-looking, middle-aged German, sitting in his room as if nothing was the matter with him. He said that he felt quite comfortable, except that he was weak. The history which I elicited was that, thirteen years before, he had a severe attack of pain in his left flank which was followed by fever, confining him to bed for some weeks; after which he recovered, and remained well till, in the night, eight days ago, he had another attack of the same kind of pain come on in the right side, soon after which he could pass no water; and his physician found no urine in his bladder when he catheterized him. My examination of the patient elicited scarcely anything but negative signs. His temperature was normal, his pulse normal and not of high tension; he complained of no cerebral symptoms whatever, and had slept well nights; he had no bronchial or pulmonary symptoms of any kind; and nothing had gone wrong with his stomach or bowels, except entire loss of appetite, with some constipation. The only symptoms that I could discover were that his pupils were symmetrically contracted, and that there were slight twitchings in the muscles of the face and of the hands. On retiring to consult, I told his physician that his was undoubt-

*Address before the Medical Association of Greater New York, January 12, 1903.

edly a case originally of calculous obstruction of the left ureter, which ended in the destruction of the left kidney, in his attack thirteen years before; and that he had been getting along with one kidney ever since, till that had become shut off from the bladder by a similar plugging of its ureter; and that the only thing which would save him was to cut down on the ureter and free it of its obstruction. My colleague, however, could not understand why, if my diagnosis was correct, the man did not show any symptoms of uræmia. I replied, that he would die without probably any of the ordinary symptoms of uræmia; and so he did two days afterward, because the physician refused to have any operation attempted. I learned that the patient was conscious to the end, had neither convulsions nor coma; no dyspnœa, nor pulmonary œdema; no vomiting, nor intestinal symptoms; and not a sign of dropsy about him. His only symptoms were increasing weakness and a slight increase in muscular twitchings, until he died of pure asthenia.

Now, one important inference from such a clinical history is this: that the fatal poisoning in this man, and in similar cases, was *not* poisoning by what we know as uræmia. There is fully as much difference in the accompanying symptoms between the two conditions, as between poisoning by morphine and poisoning by strychnine. We must conclude, therefore, that the poison, or poisons, of uræmia must be different in kind and in composition from those which operate to destroy life when the secretions of the kidneys are suddenly and totally suppressed.

And so undoubtedly they are. But, what is more, a careful study of the great variety of symptoms of uræmia itself in different patients suggests the inference that there must be a corresponding variety of distinct poisons present in them, some of which it may be possible to recognize by their own special properties, just as we would recognize any of our drug poisons by their special properties.

A priori, we might expect this to be so, because as the poisons of uræmia originate presumably in the disintegration of tissues, so modern chemistry has demonstrated that different poisons may arise in the decomposition of the same tissues. Thus two distinct poisons have been isolated from nervous tissue, choline and neurine, and their presence has been detected in the cerebrospinal fluid drawn off during life in patients with degenerative nervous diseases. Of these two poisons, neurine is much the most virulent, and with different properties from those of choline.

So in uræmia I believe that we have, among others, one special poison which is quite common and very important in its relations to the course of renal diseases, but which can be distinguished by its own specific effects, and what is more for our present purpose can be treated accordingly. To illustrate this, I will give the following particulars of a case: In November, 1901, I was called by my friend, Dr. Alexander Travis of this city, to see a lady, sixty years of age, well-nourished and healthy-looking, who suddenly became dizzy and fell from her chair. She had not complained of any particular symptoms before, except some dyspnœa while walking against the wind, and occasional cramps in her legs. She did not lose consciousness in her fall, but felt as if she would faint away if she attempted any movement. She passed a very restless night, and when I saw her the next day, in consultation, she presented all the symptoms of acute dilatation of the heart. Merely changing her position in bed caused cyanosis and vertigo. The left ventricle was much dilated, the heart impulse could not be felt, at the apex the sounds were very indistinct, at the base the aortic second sound was accentuated. The radial artery felt very small, but smooth, with no signs of thickening or of atheroma. The pulse was irregular, but of very high tension. The urine was scanty, with a faint trace of albumin, and with granular and hyaline casts, but no red blood-cells. As the indications were to relieve the vascular tension and to stimulate the heart, every variety of vasodilators and of cardiac stimulants were successively tried for two months, during which I frequently saw her with Dr. Travis, and we faithfully used the nitrites, including the tetranitrate of erythrol, along with strychnine, caffeine, sparteine, strophanthus, and digitalin, besides sodium iodide, arsenic, and tincture of iron, but without avail. The patient continued being unable to have her head raised, while uræmic gastrointestinal symptoms became very troublesome, with alarming attacks of dyspnœa and syncope, mild delirium, pains in the head, and convulsive twitchings of the muscles of the face and extremities. She had a urinous odor about her, and the diarrhœic movements were very offensive. The pupils remained symmetrically contracted. The urine continued to be deficient in amount, and the daily output of urea, which was constantly estimated by Dr. Travis, sank down to 120 grains, or 8 grams.

At this stage of the case I advised an entire change of treatment, and recommended that she should be put on full doses of aconite, five drops of the tincture every three hours. The effect of this medication is given by Dr. Travis in a note to me, as follows:

"1903.—In a few days improvement in all her symptoms was perceptible; her digestion became better; mental and nervous symptoms disappeared; the arterial tension disappeared; the daily output urea arose from 120 grs. to 480 grs.; the character of the heart action improved; the apical impulse became perceptible, and slowly increased in force, and the pulse became regular and fuller. Within a week the patient sat up, supported by a bedrack, for ten minutes, without marked change in the pulse.

"The aconite was continued for six months in the same doses. The patient slowly improved and sat out of bed from six to eight hours daily, going out to drive, and taking other gentle exercise. Twice the dose of the aconite was reduced, but the return of high tension and diminution of the urea output to 200 grs. daily, with return of symptoms of cardiac weakness, caused the resumption of the original dosage.

"At the end of six months the aconite was discontinued and the nitrites were substituted for it for one month. Cardiac weakness and high tension developed again, and the urea fell to 150 grs. daily. Aconite was again substituted for the nitrites, and again the heart action and pulse improved, arterial tension lessened, and the urea increased to 450 grs. After four months more, the aconite was discontinued, as vasodilators seemed to be no longer indicated. The patient continues to lead a carefully regulated life, makes and receives visits, takes walks and drives, and has steadily improved in strength and appearance."

I have no doubt that my prescription of full doses of aconite to this patient, whose heart was so weak that it was dangerous to raise her head, would entitle me, in the estimation of many, to a front rank among the original homeopaths. But, my reasons were that in certain common states of renal derangement, I believe that a special poison is generated, perhaps in the kidney itself, which possesses very similar properties to those of the internal secretion of the adjoining glands, the suprarenal capsules. Suprarenal extract, or adrenalin, its active principle, acts as a very powerful and universal vasoconstrictor, and thus greatly raises the general arterial pressure. I believe that this one, among the uræmic poisons, does precisely the same thing; so that its properties are indistinguishable from those of adrenalin. It is not necessary to postulate that if so the daily amount generated

must be very great to account for the high-tension pulse of kidney disease for months together, because Schaffer and Oliver have shown that nothing is so extraordinary about adrenalin as the minuteness of the dose which will act on the whole vascular system, $\frac{1}{800}$th of a grain being sufficient to affect the pulse of a healthy man. If the supposed kidney poison is at all similar, its effect would be the same as a continued over-dosing with suprarenal extract, both arteries and arterioles throughout the body would so contract that the heart would labor against a universal obstruction, until after first enlarging, it might then suddenly dilate and fail.

In this connection, it should be borne in mind that the kidneys are so liberally supplied with both vasoconstrictors and vasodilators, that they might almost be termed erectile organs. Whoever has experimented with them by the employment of a kidney oncometer will have frequent occasion to note how rapidly they can increase, and then shrink in bulk by alterations in their circulation. In an experiment at which I assisted, the enclosed kidney swelled so rapidly that it burst the drum of tambour of the recorder. Now, one of the striking results of suprarenal extract injected intravenously, Schaffer reports, is a most extraordinary shrinkage of the kidney, a condition which could not fail seriously to impair its excretion of urea. In all such conditions in disease, the employment of vasodilators is indicated, and for that purpose the various nitrites have been much used with marked benefit, particularly in increasing the output of urea. But in my opinion the ideal vasodilator is aconite. Its effect is more pronounced and much more lasting than that of the nitrites, and in this patient's case this fact was repeatedly proven, for she took very large doses of nitroglycerin, and was also subjected to the most prolonged action of the nitrites, the tetranitrate of erythrol, with only temporary benefit; while she responded at once to the aconite, with an immediate increase of the elimination of urea from 8 gms. daily to over 32 gms.; and, as noted, whenever the aconite was omitted the urea directly fell in amount. In her case, I regarded the extreme heart weakness to be directly due to cardiac exhaustion from excessive arterial ischæmia, and that by relief from that obstruction, the heart would gain much more from the rest secured from easier blood flow than it would lose by the local depression of the aconite on itself; and the event proved that my surmise was correct. The supervention of arterial contraction with consequent high-tension pulse is such an early clinical symptom in renal disorders that we must assume the presence of some such functional agent or poison to account for it. But if this agent should continue to operate for any length of time, it is equally clear that it must lead to serious organic changes in the blood vessels themselves. The fact is well-known that arterial atheromatous degeneration always affects those parts which are the sites of the greatest intravascular strain, hence any agent which persistently raises the blood-pressure must sooner or later give rise to extensive textural alterations in the vascular coats. I would ascribe, therefore, the arteriocapillary sclerosis of long-standing kidney diseases to high tension first, rather than high tension to the sclerosis. After the resulting chronic endarteritis has led to extensive obliteration of arterioles, we then have, of course, a further mechanical cause of increased tension; but this is the secondary and not the primary cause of the intravascular pressure; and it becomes, therefore, an indication of the highest practical importance to use vasodilators from the earliest stages of kidney disorders for the prophylaxis of some of the worst effects of those derangements upon the heart and upon the blood vessels.

Believing, as I do, that we have in aconite our most serviceable and safest drug for this purpose, I would recommend its systematic use as long as the pulse remains both tense and frequent, for the purpose of lessening the strain on the heart, for checking the progress of vascular disease, and for increasing the failing excretion of urea. In its employment, we should be guided by the effect produced upon the tension and the frequency of the pulse.

On the other hand, we cannot expect much from aconite, nor from any functional vasodilators for that matter, in conditions where widespread chronic endarteritis has already caused extensive obliteration of the smaller arteries. Here the pulse tension, as already remarked, is due to permanent closure of a great number of the peripheral vessels, and neither aconite, nor any similar agent, can dilate vessels which have practically ceased to exist. In cases of senile hearts, therefore, aconite should be given with discrimination. Even in them, however, should the pulse be not only of high tension but also rapid, aconite may be advantageously given till the pulse falls to normal frequency, and then intermitted, for I have seen it do much good in old people who, from their quickened pulse, appeared to have some acute exacerbation of chronic renal trouble.

In puerperal eclampsia we have a remarkable illustration of such a poison being rapidly formed and giving rise to extreme high tension. But in addition to that we have the most dangerous addition of another element, which is rapid and powerful action of the heart itself. Schaffer's experiments with intravenous injection of suprarenal extract supply a striking parallelism to this condition, for he found that if, after injecting the suprarenal extract, the vagi were cut or paralyzed with atropia, the heart then acted very violently and forced such an increased amount of blood into the contracted arteries that an enormous rise in blood-pressure followed. Excessive intracranial vascular tension then gives rise to a fatal status epilepticus unless promptly relieved. It would seem, therefore, that in puerperal eclampsia an analogous paralysis of the vagus occurs, either by over-stimulation by an excessive generation of the vasoconstrictor poison, or else by the conjoint action of some other poison resembling atropia. It is conceivable, however, that the increased heart action may be due to such a stimulation of the accelerator nerves of the heart by the original vasoconstrictor poison that the inhibition of the vagi is wholly overcome.

Clinically, the best and speediest vasodilator which we can use to relieve such a condition is free venesection, but if that be objected to, then veratrum viride should be given in very large doses, given according to the effect on the tension of the pulse and limited by no other consideration. Aconite is much too slow for such an emergency, and, besides, aconite does not have the specific effect of veratrum on the great splanchnic blood vessels. Our object is to quiet the heart and relax the arteries by bleeding the patient, as has been expressed, into her own abdominal veins, which, when fully relaxed, can hold all the blood of the body.

A number of theories have been advanced to explain the intoxication in puerperal eclampsia, among them, that it is caused by deficiency of the secretion of the thyroid gland, as it is claimed that the thyroid is enlarged in pregnancy by increased functional activity, the thyroid secretion being supposed to neutralize the poison in the blood, and it is stated that puerperal convulsions occur mostly in women who do not show this thyroid hypertrophy.

I do not incline much to this view, because precisely the same kind of convulsions, with just the same accompanying vascular symptoms, occur from acute alcoholism in men.

I was called in consultation by the late Prof. M. A. Pallen, to a man who, after drinking an enormous quantity of brandy, was taken with convulsions, in which he continued with coma for ten hours before my arrival. I found him deeply cyanosed, and with not only a rapid pulse of extreme tension, but with the most violent action of the heart. As my colleague thought we might be blamed by the friends if the man was bled and then should die, I recommended that twenty drops of the tincture of veratrum viride should be given every twenty minutes till the pulse tension gave way. Two drachms were therefore given in all, in four hours and a half, when the convulsions ceased and the patient recovered.

Widespread degeneration of visceral cells is also adduced as a sign of some special toxin in puerperal eclampsia, but this, I think, can be explained as a definite effect of arterial ischæmia, which I will allude to presently.

There are some instances of deficient elimination of urea when I would not think of prescribing aconite, and as such cases are by no means uncommon, and are apt to be very puzzling to the practitioner on account of the great variety of their nervous symptoms. I beg leave briefly to refer to them. These patients do not seem to have any organic disorders of the kidneys, and are often passed by life-insurance companies without question, but they come to us with a clinical story which is anything but clear to us, as the following short summary of the symptoms of two men, both of whom came to my office in the same week, well illustrates:

J. H. H., aged twenty-nine, merchant, had always enjoyed good health until nine months ago, when he began to have a feeling of weariness below the knees, with cramps and numbness about the calves. These paræsthesiæ lasted about a month. Then followed sensations of "drawing" in his legs, when he could not keep his feet still, these "spasms" coming on mostly after meals. He then had insomnia, became nervous and hypochondriacal, and was often dizzy on rising in the mornings. This in turn was followed by drowsiness, in which he would drop asleep in his office, and once he slept uninterruptedly from 3 P.M. to 1 P.M. the next day. His hands became so weak that he had difficulty in writing. He would also have attacks of much gastric distress, which would last a week and then pass away.

The second case was Captain J. A. H., aged thirty-seven, U. S. Army, but retired and now a mining engineer. Was on duty in Cuba, where he contracted malaria fever, followed by chronic dysentery. This subsided, but left him for two years subject to chronic diarrhœa, to attacks of irregular chills with fever, and persistent articular inflammations, like rheumatism. He went to Ecuador to superintend mining operations there, but there he suffered from an attack of delirium, in which he was comatose for two weeks. Ever since he suffers from a violent neuralgia over the left eye, radiating to the occiput, which, from its persistence, makes him distracted. No malarial organisms could be found in his blood.

Now, I think it is a safe rule, when we have a whole series of anomalous and contradictory nervous symptoms in a patient, which cannot be reduced into conformity to any definite disease, that we must then suspect a toxæmia of some kind, most likely either of renal or intestinal origin. I directed both of these patients to collect the urine for twenty-four hours, and then have a specimen of it examined for the purpose of estimating their daily output of urea. They both assured me that within the year they had taken out life policies, each in a different but leading company in this city, and their kidneys then were pronounced all right; but I found that the first one of them, whose daily output of urea should be at least 24 grams, passed only 13 grams, and the other barely 15 grams.

In both these male patients the pulse was both slow and of low tension; and just such cases are common among women, when their trouble is most certainly taken for hysteria. True, purely functional renal inadequacy, or at least inadequacy of elimination of urea, not due to organic kidney disease, is, I believe, very common, and, in my opinion, is generally dependent upon gastrointestinal derangements, and should be treated accordingly.

Thus far we have been considering symptoms of uræmia due mainly to functional derangements of the kidney, though in cases of persistent high tension the functional leads to organic disease sooner or later. The treatment of uræmia due to organic derangements of the kidney is such an extensive subject that I can only allude to some of its chief features.

First, as to acute nephritis, of which scarlatinal nephritis is the representative type, we meet as usual with some anomalies in the matter of causation. Clinically, it bears no consistent relationship with the severity of the scarlet fever itself. One of the severest cases which I have had to treat, and who distinctly desquamated three times during the course of his illness, had all sorts of intercurrent complications, except one, and that was that he never had any appreciable trouble with his kidneys. On the other hand, some of the worst cases of nephritis which I have met in consultation had their scarlatina so mildly that we had to hunt up for the proof of its connection with the case. I doubt also if any very strict precautions against exposure, etc., during the illness are of much avail in preventing the nephritis. Daily oiling of the skin with lime-water liniment and oil of cinnamon may have some value, and I always recommend it; but it is just as likely to occur in children who have shown very little desquamation as in those whose skin has been so inflamed as to cause it to be renewed all over. The best prophylactic, in my opinion, not only against nephritis, but against the disease running a bad course generally, is to begin at once at the first onset with a laxative dose of calomel, and repeat it every night till the tongue desquamates. Whenever diarrhœa also occurs, calomel stops it at once. But as the days pass we are to look out for the first danger signal from the kidneys, and almost invariably that first signal is not the appearance of albumin, or of blood corpuscles under the microscope, but a diminution in the quantity of urine, and a fall in the specific gravity.

With nephritis developed and advancing, we should energetically have recourse to the most certain of all diuretics in conditions threatening suppression, and that is the rectal douche, with normal saline at 115° F. Action of the bowels always causes a flow of urine in health, owing to the nervous association between these two adjacent viscera; and this association stands us in excellent stead whenever the kidneys are failing to secrete from any cause. I would place more reliance upon this one than upon any other single measure in scarlatinal suppression. At least two gallons of the hot saline should be allowed to run in and out at a time, the best instrument for which purpose that I know of being Kemp's rectal irrigator. I have

seen also most excellent results from hypodermoclysis of from two to four ounces of normal saline in the flank in these cases, and in the hemorrhagic nephritis of diphtheria. We need hardly despair of even the most seemingly desperate case of scarlatinal suppression.

In one patient, a boy of eleven years of age, who had suppression for six days, convulsions and coma supervened so deeply that a well-known physician who was called in from a neighboring house during my absence, pronounced the boy dead. When I arrived, I had recourse to a procedure recommended by Dr. Brown Séquard, and had tablespoons dipped in hot water till the spoons scalded the skin when applied to spots over the kidneys on the anterior wall of the abdomen. About the sixth application the boy opened his eyes, whereupon a high rectal irrigation produced a movement of the bowels and a flow of urine, which continued afterward, and the patient recovered.

Before an audience like this I need not speak of the main indications for the management of a case of chronic interstitial nephritis, and I only wish to refer to some special points connected with the subject.

It is not uncommon for persons to be suddenly taken with uræmic convulsions as the first announcement to anybody that they have Bright's disease. Post mortem we find that they had long been carrying diseased kidneys with them, with only moderate accompanying symptoms, which they had accredited to biliousness, etc. Others, on the contrary, have long been known to have kidney disease, but they have got along fairly well for many months, or even attended to business, and then, suddenly, serious symptoms develop, which soon carry them off.

I believe that in the great majority of such patients a new element has entered into the case, the recognition of which we owe to recent advances in pathology, and that new element is a septic invasion of the kidneys by bacteria, of which the commonest form is the colon bacillus. Dr. Flexner has been one of the foremost investigators who have demonstrated the rôle which terminal infections play in the final issue by death of many chronic diseases, particularly diseases of the heart and of the kidneys, so as to lead to the saying that a man does not die from his disease, but from his bacteria.

In chronic interstitial nephritis, the process seems to be this: A patient with cirrhosed kidneys, who has had polyuria for months, begins to pass much less urine, or perhaps very little. He is then beginning with virtually the same conditions as a case of commencing scarlatinal nephritis. Soon after he has a convulsion, and becomes comatose, or he has an attack in the night of uræmic asthma with œdema of the lungs and pleural effusion, or an attack of vomiting and diarrhœa. Often thereafter the kidneys stop secreting altogether, and death follows. At the autopsy the kidneys are found to be acutely inflamed, stuffed with microorganisms of various kinds, but most frequently with the colon bacillus.

There is nothing that I dread so as an attack of so-called cholera morbus in an elderly person. We should at once turn our attention to the kidneys to find out what their condition is. Something also of this kind undoubtedly occurs in those cases which heretofore have been regarded as simply an acute exacerbation of the original chronic malady. I think that I have repeatedly warded off the worst results from threatening symptoms, such as fever, mental clouding, Cheyne-Stokes' breathing, vomiting and the like, in these patients with cirrhosed kidneys, by prompt mercurial cathartics, followed every two or three hours by 10 grains of urotropin, combined with 10 grains of sodium benzoate. In my experience, urotropin never causes untoward symptoms, if sodium benzoate is given along with it Of course, hot saline rectal irrigation also should be used, as in a case of scarlatinal suppression. At least against the presence of the colon bacillus in the kidneys, urotropin is as specific as with the bacillus typhosus.

Our prognosis in all cases of chronic interstitial nephritis must always be uncertain, because we can never be sure how much working kidney substance they have left. Thus, for some three years I continuously watched an elderly gentleman, aged sixty-five, who during that time had pretty nearly everything that occurs in chronic uræmia by turns. His urine was always pale and of low specific gravity; he was nearly blinded by retinal hemorrhages; he had frequent attacks of transient aphasia or paraphasia, and local paralysis; also frequent uræmic asthma, with œdema of the lungs, and pleural effusion; once a severe attack of hæmoptysis, and Cheyne-Stokes' breathing for nights together. After three years of such a clinical history, his urine suddenly began to improve so much that I doubted if the specimen once sent was not that of some other member of the family, as it was quite normal in color, specific gravity, and freedom from albumin and casts. He continued so much better for three months that I did not see him so often, until one day I was summoned to see him in violent convulsions, from which he passed into terminal coma. I then learned that, contrary to advice, he had been eating beef heartily three times a day, as he was very fond of it and had always been a great meat-eater.

This leads me to say a word about the question of diet in this form of kidney disease especially. We properly exclude a full meat diet, when the excreting powers of the kidneys are impaired; but it is well to remember some physiological facts which relate to this subject. In health, after every meal, particularly after a hearty meat meal, the kidneys at once begin to excrete an increased quantity of urea, more than they will do in the same length of time some hours afterward. A balance is thus maintained against a too rapid increase of proteids in the circulation on the intake of food. If the kidneys from pre-existing disease are unable to respond quickly to this after-meal duty, dangerous accumulation may occur, and doubtless this may account for the attacks of apoplexy, which are often recorded after Thanksgiving or Christmas dinners. But what I particularly wish to refer to is the apparent difference in proteid metabolism between the day and the night hours. We have a whole series of affections marked chiefly by nervous disturbances, which are evidently due to various toxæmics, and all characterized by being worse in the early morning hours. Many cases of melancholia, of migraine, and all cases of Graves' disease, show this peculiarity. In Graves' disease the twenty-eight symptoms, aside from the goiter and exophthalmos, which I have found characteristic of this singular malady, are, without exception, worse in the mornings. I have records in my notes of no less than eight who could not write or sew in the morning, but could do so in the evening. In all such cases of melancholia, migraine, or in Graves's disease, I enjoin entire abstinence from red meats, especially beef, and most of all at night. Likewise the first attacks of gout and of peptic asthma are always after midnight. I have repeatedly noticed that many patients can take beef at breakfast or at lunch, but taking it at evening dinner will give them very troubled

sleep. All these particulars should be borne in mind when we aim to regulate a man's life who comes to us with a high-tension pulse and rigid arteries. Every one of such patients imposes a special responsibility on us, for what ought we try more to do than to save a fellow-man from awakening some morning with the terrible calamity of a hemiplegia upon him, when it would have been better for many such patients afterward had that night's sleep been their last.

The chemistry of these night generated poisons is yet to be worked out, but there can be no doubt that they have much to do with the changes in the alimentary canal, connected with the nitrogenous elements of food, particularly the red meats, and every person with cirrhosed kidneys should be enjoined like an asthmatic not to eat heartily after mid-day.

For the rest, I may say that the greatest remedy for autoinfection and the best prophylactic against the manifold dangers of chronic intestinal nephritis, is life in the open air. Such a case needs a milder climate in winter, just as much as any bronchitic or phthisical patient. Intestinal antiseptics are of the greatest value, and, as to special medicinal remedies, I have great faith in the employment of $\frac{1}{3}\frac{1}{4}$ gr. hydrarg, bichlorid t. i. d. for one week out of three weeks, and of small doses, not more than 5 grains, of sodium iodide t. i. d., taken for prolonged periods.

Finally, I will conclude by reference to some points connected with chronic parenchymatous nephritis. I think that it is unfortunate that two such different affections, as chronic intestinal nephritis and chronic parenchymatous nephritis, should go by the one name of chronic Bright's disease. It is quite true that the pathological anatomist cannot find a hard and fast line separating these two kidney affections. Cases of interstitial nephritis present parenchymatous changes, and cases of parenchymatous nephritis present interstitial changes. But there are no hard and fast lines in pathology, any more than in nature. But, all the same, the typical, shrunken cirrhosed kidney is as different a thing in reality as it is in appearance from the large white kidney of chronic parenchymatous nephritis, and in all their main clinical aspects, and hence, in their etiology and pathology as well, these two diseases differ and contrast with one another from the beginning and all the way through, so that they do not come together except in the terminal symptoms of uræmia.

Chronic interstitial nephritis is most commonly a disease of past middle life, and is associated with the general nutritive changes of advancing years. Parenchymatous nephritis attacks the young oftener than the aged, and is not infrequent among children. In kidney cirrhosis, albuminuria is usually insignificant in amount, repeatedly is absent, and at no time is of much import as such. In parenchymatous nephritis, albuminuria is steadily present and abundant. But above all, with interstitial nephritis, the patient is never waterlogged, unless from consecutive heart disease. In parenchymatous nephritis, from the beginning there is a tendency to a general leakage of water into the tissues, so that it appears first in the face instead of the feet, and the cause for which is so far wholly unexplained. As to the mechanism of dropsy in general, I need only refer to the three contradictory theories of Cohnheim, of Ludwig, and of Haidehain, to show how far we are from certainty on this subject. Cohnheim saw an analogy between dropsy and inflammatory exudates. Ludwig inclines to the view of intravascular pressure; while Haidenhain advocates its source as a secretion of cells. All of these theories are wholly inapplicable in the case of renal dropsy; and as an eminent pathologist, who had been an assistant of Haidenhain in his laboratory, remarked to me, we are still wholly in the dark as regards the cause of the œdema of Bright's disease.

Now, place two advanced patients of chronic interstitial and of chronic parenchymatous nephritis side by side, and can one doubt that the systemic poisoning in the one is quite different in kind from that in the other? The one, a young universally swollen, white-bodied, glassy-skinned, and thoroughly anæmic subject; the other, a thin wrinkled personage, who looks like anybody else at his age, so that you are not on the track of his trouble till you have heard a full clinical history and then can make a thorough examination.

It is, however, when, at autopsies, we take the kidneys in our hands that we learn how different the problems of treatment are in each case. The capsule of the tough, cirrhosed kidney has become almost an integral part of the shrunken organ, it so dips into and adheres to the kidney substance that we have to tear away bits of this to strip it off. The capsule of the large white kidney is stripped off the soft organ as readily as an orange rind. But it is within the white kidney that we find why most of our therapeutic measures are so inefficacious. The glomeruli are pressed upon by masses of the round cells, which fairly stuff Bowman's capsules, and the tubules are choked by every kind of débris. Now, it would seem that if we only had the double circulation of the lung, all this ruinous accumulation might be got rid of. We have interstitial pneumonia, if the lung exudates are not removed, just as we have interstitial nephritis also in the kidney if it remains clogged with inflammatory exudates; but interstitial pneumonia is rare, because in the lungs we have the double currents of the pulmonary artery and of the bronchial arteries, and between them the immense exudates of a croupous pneumonia are got rid of, usually before the stuffed air cells are damaged. In the kidneys, on the other hand, we have the one renal artery, which answers to the pulmonary artery in the lungs, and nothing more. To expect that the kidney capsule will allow enough blood vessels to enter through it to help absorption, would be even less likely than to expect help from the blood vessels of the pleura to assist in the removal of the inflammatory exudates in the air cells.

We seem, in this condition, to have an obstacle which wears the aspect of a mechanical obstruction quite insuperable to our ordinary medical remedial measures. The attempt to increase the outflow of watery urine by diuretics against the dropsy oftener fails than succeeds. We may temporarily succeed, by trying one diuretic after another, but the cause of the dropsy remains, and the œdema returns just the same as ever. All we can do then is to ask skin and bowels to do extra work vicariously for the kidneys; but in the majority of instances we make no real headway. Some patients with chronic kidney disease, with dropsy and persistent albuminuria, recover; but whether they do so on account of our therapeutics, or whether they recover spontaneously, we cannot tell.

When confronted by such difficult conditions as these, physicians ought readily to advise with the surgeon whether he can do anything. It was, therefore, with great interest that I read the paper by Dr. George M. Edebohls of this city, published in the MEDICAL RECORD a year ago, about operations on the kidney for the express purpose of curing

Bright's disease itself, and not merely for local purposes, such as to relieve intracapsular tension, as was done by Reginald Harrison years ago. The narration of Dr. Edebohls' successful cases would, for me, have had only the interest of simple empirical facts, the estimate of the value of which awaited further confirmation by himself and by others in other examples of the disease, but for one statement which seemed to illustrate a principle. That statement was that in the circumjacent adhesions about the kidneys where he had performed the operation of nephropexy, he found that enlarged arterial twigs had developed leading into the kidneys, and that by going further and stripping off the capsule from the kidney, and replacing it in its bed, new vessels would be formed, thus bringing a new supply of arterial blood to the organ in addition to its renal artery supply. I can understand that by this surgical procedure we may artificially add another absorbing blood current to the embarrassed organ, and I can only hope that further experience will confirm this anticipation. I can well see that this operation may also be of service on the same principle in some cases of interstitial nephritis.

I might add a word, in closing, on the subject of albuminuria. I need not say that there have been many theories propounded about the genesis of albuminuria, but to my mind one of the best contributions of experimental medicine to this subject was the observation of Overbach, which has been amply confirmed by other experimenters, that simple clamping of the renal artery in dogs for forty minutes was followed by albuminuria for twenty days. This would seem to imply that even a temporary shutting off of arterial blood from the renal cells so damages them that they do not soon recover their normal integrity. It would seem, therefore, possible that inflammatory cellular accumulation around the glomeruli of the kidney might interfere with their supply of arterial blood by compression, to much the same degree as clamping the renal artery would. All conditions, in fact, which cause such a mechanical effect would also cause albuminuria, whether of an inflammatory nature or not, as we find in amyloid kidney. Amyloid material is neither the product of inflammation, nor even of cell degeneration, for it is essentially an intracellular infiltration of a foreign substance, which, by its mechanical pressure, causes persistent albuminuria, the same as in either an acute or in a chronic parenchymatous nephritis.

Albuminuria was once considered synonymous with Bright's disease, but it is only a symptom the significance of which greatly varies. I have a patient who has been continuously under my observation for twenty-two years, and whose urine is never free from a notable quantity of albumin, but who remains the picture of health, and who likewise asserts that he is quite well.

In the management of a case of general renal dropsy, with abundant albuminuria, I may add that I have repeatedly noticed the kidneys start up, as it were, and carry off the water when milk and a fluid diet were given up, and solid food, including even meat, given instead, with a restriction of liquids. The effects of such a change in regimen, however, should be watched carefully.

As to diaphoresis, the subcutaneous infiltration makes the skin tense and glossy, and thus closes the sweat ducts, whose opening on the surface is at an angle. A thorough oiling of the skin, therefore, before using our diaphoretic measures makes them much more effective.

A STUDY OF THE RECTUM, WITH REFERENCE TO THE CAUSATIVE FACTORS OF OBSTIPATION (WITH DEMONSTRATIONS.)*

By LOUIS J. HIRSCHMAN, M.D.,
DETROIT, MICH.

In taking up the study of the rectum, I am well aware of the fact that it is a subject less thought of, and less talked of by the general practitioner, than almost any other subject of equal importance. In fact, the rectum, to the average practitioner, is a sort of "Darkest Africa," or unexplored continent.

To a builder, in constructing a house or institution, one of the most important questions is that of proper drainage and sanitation. The most wonderful structure that has ever been in existence is the human body. While it is true that we are not builders, yet upon us, as medical men, devolves the responsibility of the proper care of this structure. Just as much as the success of the builder depends upon the healthful and habitable condition of his structure, so too do the health, welfare, and happiness of man depend upon the proper care of his body.

The question of proper elimination, or drainage of the human system, is, perhaps, only next in importance to that of its nutrition. Anything, therefore, which interferes with a proper elimination of waste products from the human body is something which demands our prompt and early attention.

In taking up the study of the rectum, I realize full well that a great deal that I may have to say at this time must be taken for granted, but I shall endeavor to demonstrate that my assertions are based on absolute fact. The most difficult questions in the vast realms of surgery and medicine are those in which reflex disturbances are involved.

One of the most prolific courses of reflex disturbances is the alimentary tract, and particularly that part of the alimentary tract which is confined within the limits of the rectum. We all know, or we all should know, that numerous diseases referred symptomatically to the genital tract, the digestive tract and other more remote parts of the body, are due largely to disease, the pathological origin of which is in the rectum. Cases of sciatic pain, incontinence and retention, as well as cases of herpes, and even nasal symptoms, have been remedied by the removal of the causes which were found in the rectum.

It is only within recent years, within the last decade or two, that the largest strides have been made in the study of rectal diseases and their remedies; and, to men who are yet in their prime, as practitioners, is due to a large extent our present knowledge of advanced rectal therapeutics—Martin of Cleveland, Otis of Boston, and Pennington of Chicago are among those men who have recently contributed to our knowledge in this quarter.

Now, what is meant by the term obstipation? Obstipation, to my mind, is best described as difficult defecation, due to mechanical obstruction; which obstruction resides in the rectal wall, or in some organ which impinges upon the rectal wall. Obstipation, in contradistinction to constipation, it will be seen, is a purely mechanical condition. Constipation, however, is a condition which is usually caused by dietetic error, or some closely

*Read before the Lambton Medical Association at Petrolea, Ont., on October 8, 1902.

allied condition, or to atony of the muscular coats of the intestine, thereby weakening its propelling power. Obstipation, we have found, by observance of a large number of cases, is at the foundation of a great many different diseases. Any abnormal condition which is due to defective elimination may be caused by obstipation. For instance, uric-acid conditions, intestinal indigestion, with accompanying gaseous disturbances, palpitation, sciatica, acne, furunculosis, and other skin affections, as well as numerous other single reflex symptoms, have been traced directly to obstructed elimination.

These conditions have been relieved by the relief of the obstructed condition of the rectum. One who has devoted some considerable time to the study of the rectum is often astonished by the therapeutic "groping in the dark" which has been indulged in by seemingly conscientious and faithful practitioners of medicine. I have known cases upon cases of individuals who, suffering from organic obstruction, have been dosed with cathartic after cathartic, and enema after enema, and never in the whole course of the patient's trouble has a rectal examination ever been suggested. In a great many cases in which a rectal examination has been made, that examination has usually consisted of the mere insertion of the forefinger into the rectum, or, perhaps, also, the insertion of an ordinary dilating speculum in the lithotomy position or perhaps with the patient leaning over a chair or table. This was called in almost every case a "thorough rectal examination."

Now, before any man can conscientiously treat any condition of the rectum, no matter how simple, it is his bounden duty to the patient and to himself, as a careful practitioner, to make a thorough examination of the rectum. I maintain that a thorough examination of the rectum cannot be made without special instruments and without the patient assuming a special posture. A very fair examination can be made without any instrument; that is, with the patient in the knee-chest position and the insertion of both index-fingers, well lubricated and back to back. By slowly separating the fingers the rectum can be inflated and a fair knowledge of its condition obtained. But a thorough examination requires, as I have said before, special instruments and special care. The technique of a thorough rectal examination is as follows:

The patient should be placed in the Sims' position on an ordinary surgical table or chair. He should be raised to the knee-chest position, with his buttocks well protruding. He may be turned so that he rests upon one shoulder or the other, for comfort's sake. First, a complete ocular examination of the external parts should be made; the anus should be well inspected for fissures, external hemorrhoids, or fistulæ. The ischiorectal space should be both examined ocularly and palpated. Then a digital examination of the rectum should be made with the carefully annointed finger. A vaginal examination in the case of the female should be included in this position, for often the impinging retroverted uterus, or prolapsed ovary, may be the cause of the entire difficulty.

After having carefully done this, a rectal speculum should be inserted. When the obturator is removed, the atmospheric air rushing through the speculum into the rectum will inflate the rectum with a sharp hissing noise. I say the rectal speculum should be inserted. In reality, if the speculum is pressed against the anus, slightly downward, toward the umbilicus, and the patient asked to bear down, the anus will climb down over the speculum, and it will enter the rectum painlessly. I might say that if the patient is neurasthenic, or the anus painful, the injection of a few drops of a one per-cent. solution of cocaine will render the insertion of the speculum painless. The speculum should be first entered to its fullest length; then, by means of reflected light from the head-mirror, or, better, by means of a small electric headlight, ocular inspection of the rectum may be made.

If the rectum seems to be terminated at the end of the speculum, this apparent obstruction is probably due to the presence of a rectal valve. Now, by proper manipulation of the speculum, the edge of the valve will be brought into view, and beyond this will be seen a cavity. At the end of this cavity we may meet with another obstruction, and again moving the instrument to one side or the other, a new field will come into view. There may be two or three, or even four, such fields. These fields are known as rectal chambers, called from without inward, first, second, third, etc., rectal chambers. These chambers get their numerical name from the valves, behind which they are situated.

After we have satisfied ourselves as to the condition of the valves and chambers, noted whether or not the valves are enlarged, thickened, inelastic, or not; also, whether mucus is clinging to the valve edges, and also whether there is a polyp or ulceration in any of the rectal chambers, or not; in fact, after complete ocular inspection of the rectum with the speculum, thus deeply inserted, we may gradually withdraw it.

We must note the new fields as the side-walls come together over the opening of the speculum, observing whether or not the rectal wall is congested or ulcerated, or whether hemorrhoidal conditions exist. I might say that a very good view of the sigmoid flexure can be obtained by means of this inflation. The question of the ready inflation or not of the rectum is a point of some diagnostic significance. The appearance of the valves is well illustrated (diagrammatically, of course) by the accompanying chart.

Now that we have acquired a fair conception of the technique of a proper rectal examination, we might, with profit, discuss the various conditions which cause obstipation and which are diagnosed by means of such an examination.

Obstipation, which, you will remember, is an organic obstruction, is caused occasionally in elderly men by enlargement of the prostate gland. The diagnosis of this condition can be made by digital examination alone and needs no further comment. In women, particularly those who have borne children, or who have an enlarged womb or pathological enlargement of the other pelvic organs, who are suffering from rectocele or from adhesions of the rectum to the womb or other organs, may suffer from obstipation, due to these conditions. These conditions may also, in a large measure, be diagnosed after a vaginal and rectovaginal examination, without the need of rectal inflation.

But, by far, the vast majority of cases of obstipation is caused by the enlargement of one or more of the rectal valves. There formerly was a great deal of discussion and question as to the existence of the rectal valve. Some men, and quite recently, have declared that these so-called valves were nothing more than folds or rugæ. But, I have yet to find one of these skeptic individuals who was of the same opinion after a proper rectal examination. In fact, their statements of the non-existence of the valves were based wholly upon ancient textbook knowledge and not upon the results of modern investigation. The proper way to convince anyone of the existence of anything is to demonstrate such

an existence. Therefore, in order to explain more fully the rectal valve and its affections it is almost imperative to do so by means of actual demonstration upon the patient. In the absence of a patient or subject, by a little stretch of the imagination, my chart may help us out.

To come back to the condition which most continually is the cause of obstructed defecation, the enlarged rectal valve.

If a patient comes into your office and complains of the following train of symptoms, or some of the following symptoms, you may be justified in asking that patient to submit to a rectal examination before a correct diagnosis can be reached:

First, of course, inability to defecate properly or comfortably. The patient will tell you that he has a desire to go to stool, but strain as he will, he can pass nothing, or perhaps a few small, hard, apparently broken-off pieces, or a long, ribbon-shaped stool, accompanied, or not, with mucus. He will also tell you that this condition has existed for a long time; that cathartics have lost their effect; that he is continually suffering from abdominal distension; that he does not get relief from the ordinary defecation; that his rectum feels hot and burning, and "constantly overloaded and stuffed," as he expresses it. The ribbon-shaped stool I consider as almost pathognomonic. The patient may go from two days to a week without stool, unless aided by artificial means. There may be tenderness in the lower abdominal region. A mass can often be felt in the region of the sigmoid flexure. I have had several patients who have come to me with a diagnosis of stricture of the rectum, made by passing the rectal sound, and from the presence of ribbon-shaped stools. Proper rectal examination, however, showed them all to be cases of obstipation due to hard, fibrous, enlarged rectal valves, section of which gave complete relief.

After the relation of symptoms, such as this, rectal examination will show, in nine cases out of ten, one or more enlarged rectal valves.

The symptoms of straining, with the inability to accomplish anything, is explained by the fact that the enlarged rectal valves, overlapping, impinge one upon another during the bearing-down movement and absolutely obstruct the passage of the fæces. Perhaps if the two rectal valves do not completely appose, a narrow, elliptical opening may be left, through which the ribbon-like stool is molded. If the propulsive effort is intermittent we have a broken-off stool. The symptom of abdominal distension is due to the gases retained behind the fecal mass in the large intestine, which, in its turn, is retained behind the valves. The general symptoms are those of intestinal autointoxication and the other diseases due to defective elimination.

I might say that, in my opinion, the enlargement of the valve, in the first place, is due to a condition of congestion, which is caused by straining to remove the stool, which is composed of improper food elements or improperly digested food. The constant hyperæmia is conducive to an overgrowth of tissue in the rectum, as well as in other parts of the body.

Now, what shall we do for our patients who are suffering from obstipation? Advise proper diet? Advise exercise, massage, the drinking of large quantities of water, out-door life?

Yes, these are all good suggestions to our patients; but all of these will not remove a mechanical obstruction. If the obstruction is due to enlarged prostate and the case is operable, operate. If not, our patient is, indeed, in a sad plight. Most of the conditions in the female pelvis are amenable to surgical relief. Tamponing in some few cases will bring the needed relief. My experience, however, with tampons has been grievously disappointing in these cases. In some cases, in which the rectal valve is slightly enlarged, massage, by means of a probe covered with cotton at the tip, will, if practised daily, bring about a gratifying result; but, in a large number of cases, the enlargement has gone on so far that, when the case comes to us for treatment, operative relief is the only treatment left.

The enlarged rectal valve, which is the offending member in these cases, can be safely incised through the speculum by means of special instruments which I have devised, and which I herewith exhibit.

We may use general anæsthesia, local anæsthesia,

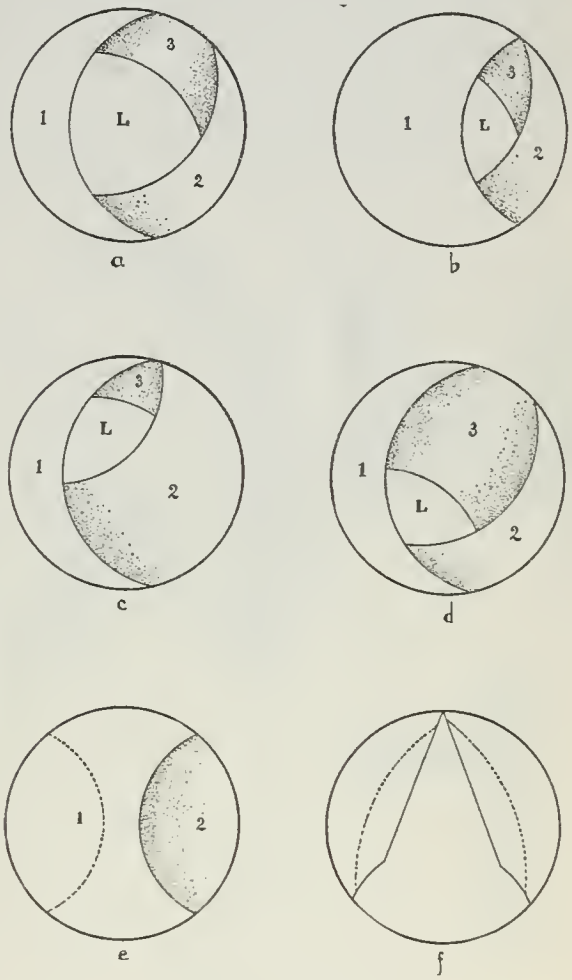

FIGURE 1 (Diagrammatic).

(3) Third rectal valve.

or operate without anæsthetics at all, for it may not be generally known that the upper rectum is not supplied with sensory nerves, and I frequently operate without an analgesic agent of any kind.

The technique of the operation is simple after one has made a study of the subject: and, robbed of its details, it is as follows:

A V-shaped incision down to the base of the

offending valve is made with the angular rectal scissors. The cut edges are then engaged between the jaws of my valvotribe, and are crushed to such an extent that hemorrhage is stopped. We next proceed to the higher valves until all the diseased ones are treated with in like manner. I used formerly to employ this hook-shaped needle, armed with a catgut suture, with which I tied off the valves before cutting them. The suture was retained in place by means of perforated shot. I devised a valvotribe to do away with the stitching, and it has been eminently successful, greatly shortening the length of the operation. The rectum is then packed with sterile gauze through which a rubber tube for the passage of gas is inserted.

The patient is usually required to remain in bed from three days to a week. At the end of twenty-four hours the gauze packing, with the tube, is removed. The patient is allowed to remain on liquid diet for forty-eight hours longer, and is then allowed gradually to resume regular solid food.

I have found that in from one to two weeks the patient has fully recovered, a natural bowel movement coming on unassisted within forty-eight hours

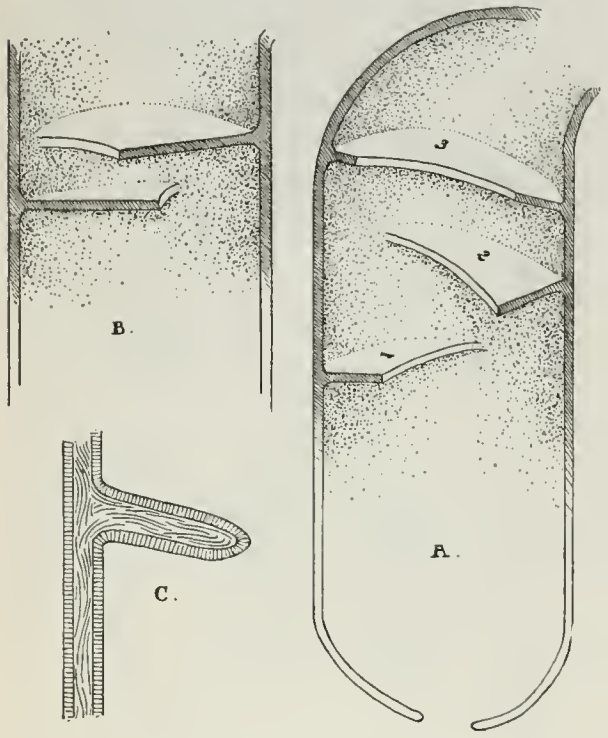

FIGURE 2 (Semi-diagrammatic).

(*A*) Longitudinal section of normal rectum, showing normal size and relation of rectal valves to each other.

(*B*) Longitudinal section of rectum, showing enlarged first and second rectal valves overlapping (the enlarged valves are very much more thickened than the diagram would indicate).

(*C*) Cross section of rectal valve (enlarged), showing muscular structure.

of the operation, and the patient seldom requiring any cathartic assistance afterward. I have had some cases in which this condition had existed for from fifteen to twenty years and natural bowel movements have resumed immediately after the operation.

In the relief of this condition and the providing of proper drainage for the human economy, I believe that we, who have explored the heretofore unknown and seemingly unapproachable fastnesses of the human rectum, have accomplished a considerable deal toward the happy existence of the human race.

420 WOODWARD AVENUE.

IS THE GALL-BLADDER AS USELESS AS IT IS DANGEROUS?

BY WOODS HUTCHINSON, A.M., M.D.,
PORTLAND, ORE.

SOME seven or eight years ago, while engaged in a study of the alimentary canal and its appendages, from the point of view of any possible relations between their history and their disease tendencies, my attention was attracted by the singular position occupied by the gall-bladder. The points which especially attracted my attention were the familiar ones of its small size, thick and inelastic wall, disadvantageous mechanical position, and marked tendency to disease in our own species.

When I came to consider its relation in other mammals, and in the animal kingdom generally, its position became still more puzzling. Although dating from a very early period in our probable ancestral tree, being well-developed in the amphibians and in most fishes, even in as primitive a form as the lamprey, it never at any time in the course of this series shows trace of more definite function than is now possessed by it. Furthermore, when we come to compare its size and presence in the different species and families of animals, we are instantly struck by the singular fact that it is one of the most inconstant appendages of the alimentary canal. Roughly speaking, it may be said to be present in the majority both of classes and of species in any given class; but at the same time its disappearance will occur in species not merely of the same class or family, but even of the same genus, without any apparent ascertainable reason. For instance, among some of the best known animals; it is *absent* in the horse, present in the cow and the sheep; it is present in the goat, *absent* in the deer. Among birds, it is present in the hawk and owl, *absent* in the dove family. And so it might be followed through a long series of contrasts, in animals, in many instances closely related, and in other instances, living upon almost identical foods, in which the gall-bladder may be either present or absent, without any apparent rhyme or reason. The only rule that could be laid down at all is that it is generally present in carnivora, whether birds or mammals, and that its variations chiefly occur among the herbivora; but even this is not without exceptions.

My post-mortem studies in the zoological gardens of our eastern seaboard still more strongly aroused my suspicions as to the vital necessity of this structure, and when I obtained access to the large amounts of material in the gardens of London, Berlin, and Leipzig, my suspicion began to arise to the dignity of a theory, that the gall-bladder was practically a functionless organ, and probably vestigial.

This, of course, was purely from a morphological point of view, although the facts even then known as to its decided liability to morbid changes had their weight in strengthening my suspicion, but two other contributions from the practical and clinical sides of the problem, finally crystallized my suspicion into an opinion. These were, first, the remarkably constant relation which has been found by Naunyn, Welch, and others to exist between the formation of gallstones and bacterial invasion of the gall-bladder, and last, the striking and brilliant paper of Roswell Park, which appeared a few months ago in *American Medicine*, entitled "Why Not Treat the Gall-bladder As We Do the Appendix?" His position is one which I think can be cordially endorsed from a comparative and morphological point of view, so far as our knowledge goes. The two organs appear to me to be

in almost absolutely parallel and identical case —the gall-bladder has the slight advantage of appearing to have some trace of function at present, which the appendix lacks utterly. On the other hand, the appendix has the advantage of a past history of distinct functional usefulness, while the gall-bladder seems to be almost destitute of such a pedigree.

The chief objection to regarding the gall-bladder as vestigial resides, to my mind, in this last fact, that we have no certain evidence of its ever having had a function whose value was in any way compensatory for the dangers to which it exposed its possessor. Wherever its diseases are susceptible of accurate study, its tendency to the formation of gallstones seems to be about the most striking part which it plays in the drama of vital activities. Indeed, in our own species, I think we would be comparatively safe in saying that the principal secretions of the gall-bladder are mucus and gallstones.

I am aware that these views will appear to be decidedly iconoclastic, and perhaps insufficiently based, but they are advanced simply tentatively, and for the purpose of eliciting what can be said upon the side of the present usefulness or value of this interesting little organ.

First of all, what can be said as to the present function of the gall-bladder? Our knowledge of it may be very briefly stated: that it lies as a lateral sac or side-channel upon the main bile duct; that it has, like all other parts of the intestine from which it is derived, a mucous and muscular coat, and that this mucous coat is thrown into an elaborate series of spiral folds. Our first impression as to its function would, of course, be that it was intended as a sort of storage bulb for any excess of secreted bile, or for its retention during periods of hepatic activity when the bile was not needed in the intestine; and this is, indeed, the theory usually laid down in the textbooks on physiology. A second glance at the organ, and that of the briefest will, however, reveal at once the serious, and to my mind, fatal defect in this explanation of usefulness, and that is the ridiculously inadequate capacity of the pouch. Its utmost capacity is from an ounce to an ounce and a half—possibly, under great distension, three or four ounces; and the amount of bile secreted in the twenty-four hours is estimated at not less than three pints, and by some investigators as high as five, or even six, pints.

In other words, our alleged *reservoir* can contain only from one-thirtieth to one-twentieth of the secretion which it is supposed to store up; or, to put it differently, if the secretion of bile be supposed to be evenly continuous through the twenty-four hours, its capacity is barely adequate for about thirty-five minutes' flow of the fluid! And even the fact that the secretion of the bile is not continuous, but probably synchronous with intestinal digestion—at least in its most rapid formation—in no way relieves the difficulty, inasmuch as it cuts down the time of possible delay, diminishing the power of the gall-bladder by just so much as the rapidity of the secretion is accelerated. When the bile is in full secretion, it would probably not be too much to say that the gall-bladder would be able to delay its flow barely ten or fifteen minutes!

The next explanation, or alleged function, which is usually attributed to it is that it in some way acts as a sort of regulator of the tension of the bile-flow. But this, we fear, will be found to be almost equally groundless. In the first place, of course, no bile whatever can enter the gall-bladder unless the circular fibers about the ampulla of Vater are contracted, or in some way the bile is prevented from entering the intestine, so that as long as the bile is flowing freely into the intestine, the gall-bladder can exercise no influence whatever upon the pressure. Supposing, however, that before the flow of bile into the intestine begins this constriction has taken place, and the gall-bladder has been fully charged with bile. Even now it is difficult to imagine what influence of any importance it can exercise upon the tension of the flow, for we have, first of all, the fact that the gall-bladder has to act in opposition to gravity, its fundus being by far the lowest part of it; in the second place, that it is more or less sharply curved upon itself by the abnormal curvature which the erect position of our species has given to the under surface of the liver; third, that its mouth is obstructed by an exceedingly elaborate and prominent series of folds in the mucous membrane, the so-called valve of Heister; last, and most damaging of all, its muscular coat is so comparatively thin, the attachment of its external coat to the under surface of the liver so universal, and there is such a marked admixture of inelastic, white fibrous tissue in the muscular coat itself, that its propulsive power must be exceedingly slight. Indeed, I think it would not be too much to say that if the gall-bladder succeeds in moving the bile, with which it is passively charged, with sufficient rapidity and frequency to keep it from actually stagnating, it is doing about as much as can be expected of it.

Last of all, we have the statement that the thick, swollen mucous coat of the gall-bladder has the power of adding to, or in some way modifying the composition of, the bile which is contained in it. Careful analyses, however, of the bile which has been taken from the gall-bladder, as compared with that which is passing along the common duct above the entrance of the cystic, shows that the principal changes are a marked increase in the specific gravity of the bile, due, in the first place, to a simple loss of water, and in the second, to the addition of a considerable amount of viscid mucus. The loss of water, although it has concentrated to some extent the bile salts, has in no way increased their efficiency or digestive value, and the mucus is apparently utterly inert and of no known value to the function of the secretion which it dilutes. Indeed, its principal action would appear to be that of clogging the already easily-obstructed mouth of the organ which secretes it.

It might also be said in passing that our theory of the value of the gall-bladder has suffered an even greater shock than any of the arguments alluded to above, in the serious doubt which has been cast in recent years upon the value of the bile as a secretion. Although this is not the place for its discussion, I have no hesitation in confessing that, in my opinion, the bile is chiefly excretory, and represents mainly waste products secreted by the liver in the course of its destruction of the toxins and ptomains brought to it by the portal blood; that another considerable moiety of the bile is made up from the destruction of the red blood-cells in all the tissues of the body, as the brilliant researches of Croftan have shown, the resulting pigments being picked out of the blood by the liver, as the urea is picked out by the kidneys; and that the free flow or obstruction of the bile is chiefly of importance as an index of how completely the liver is performing its other and infinitely more important function as a toxin-destroyer. So that, from this point of view, the gall-bladder is a small and

sluggish side-pouch upon the course of an excretory duct.

These serious doubts as to the functional value of the gall-bladder are, I believe, strongly supported from the side of clinical experience. First of all, we have the striking fact of the high disease-liability of the organ. This nowadays has come to constitute in itself a strong presupposition of comparative absence of function and consequent lack of vitality. To take its most striking disturbance, alone, that of the formation of gallstones, the results of our dissecting-room and post-mortem room autopsies show gallstones to be present in from 5 to 7 per cent. of all males, and in from 12 to 20 per cent. of females. Many of these, of course, were entirely unrecognized during life, but since we internalists have been familiar with these anatomical findings, while in addition our surgical brethren have called our attention so strongly and vigorously to the importance of gallstones, it is not, I think, too much to say that we are coming to regard the gall-bladder as a possible source of intestinal or gastric disturbance in a very considerable percentage of our cases, particularly of the motor disturbances of the stomach. Certainly in every case of digestive disturbances of long standing, especially if accompanied by pain or disordered gastric or intestinal motility, we examine with great care in two regions, first, that of the gall-bladder, and, second, that of the appendix.

When we come to consider the causation of the formation of these secretions, their occurrence becomes even more significant. Consisting, as they do, of one of the constituents of the bile which has been precipitated, it was supposed at first that nothing more was required than a certain amount of stagnation and mucoid thickening of the bile. Investigation and careful experiments upon animals (Gilbert, Fournier), however, showed that their formation did not occur even where these conditions were artificially produced nor always even upon the introduction of some small particle of foreign body to serve as a nucleus; but that wherever and whenever certain bacteria were introduced into the gall-bladder, the formation of the calculi was almost certain to follow. At the same time, bacteriological study (Bouchard, Terrier, Bloch) of freshly removed gallstones showed in almost every instance the presence of one or more species of bacteria, often those normally inhabiting the intestinal tract. In other words, the gall-bladder is purely passive in the formation of its principal pathologic product, and often seems to serve as a suitable breeding ground for certain groups of bacteria which have reached it from the intestine.

Its next most common disease liability, but one which is assuming greater importance, and found to occur with greater frequency every day, is that of acute inflammation of its mucous coat. Again we have precisely similar causation—an invasion of this dilated and stagnant pouch by some form of pathogenic bacteria from the intestinal tract. Here we have a striking parallelism between its behavior and that of the appendix. In both cases it is not even necessary that the bacteria should be pathogenic forms—the ordinary bacterial flora of the intestine are sufficient, particularly the *Bacillus coli communis*. All that is apparently necessary in both cases is that this usually non-pathogenic form should succeed in finding its way into a stagnant part of the intestinal canal, where the free return of its products to the general intestinal circulation is cut off, and it will rapidly begin to assume pathogenic properties. Supplied with an abundance of nutrient material, warmth and moisture, and to a considerable extent protected from the action of the phagocytes, it rapidly sets up a fulminant type of inflammation, in both the appendix and the gall-bladder.

It may be nothing more than coincidence, but I cannot help noting that just as something like 90 per cent. of all the perforations in typhoid fever are within 14 or 15 inches of the ileocæcal valve—in other words, where the sepsis from within could be aided by infection from without the gut, by contact with the tip of an inflamed appendix—so in the stomach 70 per cent. of all forms of ulceration will be found within three or four inches of the pylorus, in the region over which infection could be readily diffused from an inflamed and leaking gall-bladder. The readiness with which a cholecystitis will be set up in the course of an attack of typhoid fever, of pneumonia, of septicæmia, or even of acute coryza with intestinal symptoms, points to the readiness with which the gall-bladder may become the site of lodgment of pathogenic germs. I have recently seen, in consultation, within the past few weeks, a case of typhoid fever which was ushered in by profound jaundice and marked tenderness and swelling in the region of the gall-bladder.

Cushing reports that 30 per cent. of the patients operated upon for gallstones at the Johns Hopkins Hospital had suffered from typhoid fever, while Ochsner finds that from 35 to 50 per cent. of his recent gallstone cases have had appendicitis.

The light which can be derived from the origin and ancestry of the gall-bladder shows little of positive value. It is derived, both ancestrally and embryologically, from one of the several pouches from the post-gastric region of the archenteron, which give rise, first of all, to the lobes of the liver, and afterward to the divisions of the pancreas. All that can be said of it is that it appears to be one of these multiple pouches from the alimentary tract which has neither developed its secreting tissue into the large functional masses of the lobes of the liver, nor as yet completely shriveled and disappeared,, as is the case with several of these smaller primary pouches.

It has this much title to recognition as of some vital importance—it appears at a very early period in the development of the liver, almost at the bottom of the vertebral tree, in some of the lower fishes, and that in fishes, amphibia, and reptiles it is very considerably larger in proportion to the bulk of the body than it is in the higher classes—the birds and the mammals. In the frog, for instance, its capacity might be roughly stated as something like five times as great in proportion to the body bulk. But this, again, is associated with an almost equally large proportion on the part of the liver. So that, relative to the flow of bile, it would be difficult to say whether its capacity were any greater or not.

From the beginning, however, it displays very decided irregularities in both size and appearance. It is never present in more than the majority of forms in any given class, and this inconstancy appears, if anything, to increase as we go upward in the scale. In general, it may be said to be relatively larger and more constantly present in carnivora than in herbivora, both among birds and in mammals, but whether this is anything more than a feature of the usually more primitive type of carnivorous alimentary organization is a question. Certain it is that in both herbivorous and omniverous animals and birds the connection between its variations is not one of diet or habit. For instance,

in birds it is present in the whole series of the birds of prey, but variable in the ducks and other fish-eating birds; it is absent in the dove family, but present in both the domestic fowl and the turkey. One of the many curious bits of anatomical lore which have been embalmed for us, like the fly in amber, in Shakespeare's magnificent phrase, refers to this very fact. Hamlet, in one of his famous passages, alluding to the fact that the fires of his vengeance were not fierce enough promptly to wreak upon the murderer of his father the retribution which he so richly deserved, complains:

> "But I am *pigeon-livered*,
> And lack gall to make oppression bitter."

The gall-bladder was universally absent in the gentle dove, present in the ferocious hawk, and our wise ancestors, reasoning with child-like fidelity to their own style of logic, regarded the presence of the gall as the cause of the ferocity of temper. It has passed into a metaphor of similar significance, in the language of the street at the present time. If Hamlet were to appear in the vaudeville of the present day and say that he "lacked gall," his meaning would be grasped even by the gamins in the gallery, without the slightest difficulty.

Among the animals its irregulatities are even more striking and destitute of apparent cause. As already stated, it is absent in the herbivorous horse and ass, but present and well-developed in the equally herbivorous cow and sheep. And even in the much more closely related and identical, as far as food and every arrangement of the digestive tract is concerned, goat and deer families, it is present in the one, absent in the other. And its presence in the prong-horned antelope of our western plains is regarded as one of the characters assigning that animal to the goat rather than to the deer family. It is present in the domestic hog, and in the wild boar of Europe, but absent in the peccary of South America. In one species, the giraffe, it reaches such a pitch of inconstancy, that it is sometimes present and sometimes absent.

Certainly with such a record of inconstancy as this, it can hardly be asserted that the gall-bladder exercises any very vital or important function. In fact, the general tendency of such knowledge as we possess of its behavior would incline us toward the tentative opinion, that it is one of several intestinal pouches, out of which the liver and pancreas were originally formed, which has, for some reason, dilated more or less mechanically into a reservoir, instead of disappearing entirely, as did several of the other primary diverticula.

Last of all come our surgical brethren with positive and incontestible proof of our hitherto largely speculative position, that whatever may be the function of the gall-bladder in our own species, it is one that can be completely dispensed with, without serious or even appreciable injury to the individual.

Their approach to this position has been a gradual one. For many years, after an operation for the removal of gallstones, if for any reason it was not thought advisable to stitch up the gall-bladder and return it to the abdominal cavity, it was considered necessary to secure it to the abdominal wall, and form a biliary fistula. This, however, after discharging for a longer or shorter period, to the intense discomfort of the patient, was usually found to close; and where it was possible to make post-mortem examination later, it was found to have resulted in the practical atrophy and disappearance of the gall-bladder. Hence, it was timidly attempted to remove a considerable part of the structure, and to stitch down the remainder in such a way that it would probably shrivel and disappear. Later it became the habit of some of our bolder and more progressive surgeons to remove the sac completely, and finally Roswell Park, with that practical genius and keen eye for the next step in advance, which has made his enviable reputation in surgery, holds that it should be removed whenever found to be diseased, and treated as a supernumerary organ which is a source of constant danger—in short, just like the appendix. His position can, I think, be strongly supported from a comparative point of view, and I believe that the clinical evidence, from the internalist's standpoint, is almost equally strongly in its favor.

To sum up, the gall-bladder is a nearly functionless organ, inadequate in size to act as a reservoir of any value for the bile, inadequate in muscular power, and in mechanical position, to exercise any important effect upon the pressure of the bile-flow, entirely absent in many species without interfering with the processes of digestion or the vital functions in any way, capable of removal from a species in which it is normally present without noticeable injury, and chiefly notable as a settling basin for the formation of gallstones, a suitable harbor for the multiplication of pathogenic bacteria, or for the assumption of pathogenic properties by non-pathogenic forms. In short, it seems a source of danger at least double any possible usefulness which it may possess.

OCULAR SYMPTOMATOLOGY IN DIAGNOSIS

By HENRY B. HOLLEN, Ph.G., M.D.,
NEW YORK.

Since the institution of ophthalmoscopy the eye has become more and more a point of vantage in diagnosis. More than any other single organ it presents the indicative features of pathological conditions, not only of its own structures but of general disease. It is owing to the variety of its component tissues and its immediate and intimate relation to cerebrospinal centers that it becomes an invaluable field for the diagnostician. Ophthalmoscopic examination offers a means of differentiation between functional and organic disease, and in consequence is of especial service in neurological disorders. It is incomprehensible, in view of these facts, that so little attention is paid to ocular symptoms. A disregard of the eye is an offense not less pardonable in a physician than a failure to feel the pulse. Such disregard in every case characterizes the diagnosis as incomplete and unmethodical. A large number of ludicrous mistakes and oversights might be avoided and many a serious case taken early in hand were eye examination more universally made a routine procedure. Ocular disturbances are very often the first manifestations of important lesions. For instance, I have seen cases of tabes in which the eye symptoms appeared a number of years before the advent of other signs. There are instances recorded in which they were present from twelve to twenty years preceding other lesions.

It is safe to say that the vast majority of practising physicians do not make use of the ophthalmoscope, and moreover are utterly unacquainted with the conditions which it reveals. The knowledge of its principles and the riches of its interpretations seems to be in the hands of the few. Why such indifference should prevail it is difficult to say, unless it be a certain lack of confidence many possess on mistaken suppositions of intricacies which it involves. Of course, it must be said that the greatest of errors may be made in its use. A careful study of the normal fundus, and, latterly, com-

parisons with a number of pathological cases is essential to one who otherwise might be in the dark as to the appearance of the physiological cupped disc. The majority will not acquire the technical accuracy of Marcus Gunn, and, on the other hand, it might invoke detriment to the extent of overshadowing other legitimate means of diagnosis. For example, total reliance on eye findings to the exclusion of urine analysis in a probable case of granular nephritis is a procedure to be condemned.

Aside from instrumental examination, mere unaided inspection of the eyes presents many important points. The lids, first observed, will in many cases impart much information. They may be swollen, as in acute nephritis, gout, or cyst. Ptosis would suggest gummata, tabes, paralysis of the third nerve or tuberculous meningitis. On the contrary, lagophthalmos would be indicative of exophthalmic goiter, facial paralysis, or the local condition of orbital tumor. In the former, of course, the signs of Stellwag and Graefe would be of value. Dislocation would next be noticed, and, if present, might bring to mind, in case the lids appear darkened, hepatic colic or lowered nerve tone. Following the lids, inspection of the conjunctiva would be in order. Its discoloration in hepatic cirrhosis and active hepatitis is well known, but its pearly color in anæmia and chlorosis might have been forgotten. In exophthalmic goiter and ophthalmoplegia externa the eyeballs are fixed, and when nystagmus, or oscillation of the globes occurs, disseminated sclerosis, multiple neuritis, or progressive muscular atrophy may be causative factors. It is also often found in children associated with imperfect vision. Protrusion of the eyeballs, which condition is usually associated with exophthalmic goiter, is indicative here as elsewhere, of exaggerated vascular tension. Diminished vitality, well exemplified in most cases of phthisis, presents sunken eyes. Inflammations of the coverings are usually local conditions, but very often are related to diabetes or paralysis of the fifth nerve. In syphilis keratitis is present in 70 per cent. of all cases, and iritis occurs in 60 per cent.

The condition of the pupils is important, whether equal, contracted, or dilated. Broadly speaking, the small pupil is found in early stages of all acute inflammations of the brain and its membranes. On meeting with a case of contracted pupils three conditions are to be thought of, viz., drug myosis (eserine), opium habituation, and tabes. Unilateral contraction and dilatation are comparatively rare, the former occurring in aortic aneurysm, cataract and basilar tumor, and the latter, chiefly in adhesions of previous attacks of iritis in syphilis. The Argyll-Robertson pupil is an early characteristic of locomotor ataxia, and may be associated with double vision and inability to distinguish between different colors. I have found the arcus senilis in several cases under fifty-five years of age. Sachs has put forth the statement that immobility of the pupil is very characteristic of syphilitic cerebrospinal disease, and that when persistently present in hemiplegia indicates specific endarteritis.

It was Rampoldi who asserted that unequal, recurrent, transitory, papillary dilatation was an almost constant sign in tuberculosis, and Destree claims that 97 per cent. of his pthisical patients developed this sign. Oncoming mental derangement has been found by many observers to be indicated by an alternating unilateral mydriasis. Hippus, a peculiar rhythmical contraction and dilatation of the pupil, is a valuable sign, in that it may point to disseminated sclerosis, well-defined epilepsy or early acute meningitis. In differentiating these three conditions, other symptoms must, of course, be taken into consideration.

Ocular ophthalmoplegia is frequently met with. Extraocular paralyses may be nuclear in origin, when they occur usually in connection with ophthalmoplegia interna, in which the ciliary muscle, the dilator pupillæ and sphincter pupillæ are affected. Palsies are most often traceable to chronic inflammatory processes, syphilitic or tuberculous. The lesion may be anywhere along the nerve trunks, and when distally located it may be due to some orbital condition, such as cellulitis, tumor, or fracture. It is often that the eye symptoms in diabetes are those which lead the patient to consult the physician. Besides premature presbyopias, cataracts, unaccounted for mydriasis or cycloplegia, sudden and persistent amblyopia, transient paralyses of ocular extrinsics and also of the pupillary sphincters occur in glycosuric autointoxication. The relation of the uric-acid diathesis and neuræsthenia to ocular palsies in some cases would well be borne in mind. In thrombosis of the cavernous sinus there occurs paralysis of the extrinsic muscles of one side, accompanied with swelling of the corresponding eyelid, exophthalmos, contracted pupil, followed by a dilated pupil and anæsthesia of the skin of the eyelid and temple.

When subjective symptoms are present, they call attention to certain lines of investigation. Hysterical patients have amblyopia and defective color vision; in some instance, the latter consisting of a regular, concentric contraction of the visual field (homonymous hemidyschromatopsia). Limitation of the color field is found occasionally in traumatic neuroses. An irregular contraction, affecting certain colors—first, green and red; lastly, yellow and blue—is characteristic of tabetic dyschromatopsia. In migraine, while the eye symptoms occur in only 50 per cent. of the cases, they are the earliest manifestations. Asthenopia and spectral appearances, teichopsia, may be present. These spectral figures begin with a bright spot, its center fading and its edge expanding and becoming jagged, assuming a castellated form. Within the ring white spots, in rapid movement, may appear. In mild cases these disturbances are confined to mere flashes of light.

The usual symptoms, premonitory in eclampsia, are not to be forgotten, in connection with the headache and epigastric pain. In epilepsy the special sense auræ are only rarely met with. The visual aura consisting of moving balls or flashes of light, sometimes colored. In neuræsthenia, with the asthenopia, there may occur the peculiar phenomena termed muscæ volitantes.

Focal diagnosis is yet in its infancy. So far as it relates to visual symptomatology it is interesting, and a few comments might be made in passing. The anatomical decussation of optic fibers may lead to some confusion, but if the anatomy be kept in mind it is not difficult to see what portions of the chiasma are affected in various conditions, viz., unilateral nasal hemianopsia, bi-temporal hemianopsia, etc. When hemianopsia is associated with hemiplegia and hemianæsthesia the posterior limb of the internal capsule is affected. The combination of right-sided hemianopsia with word-blindness or word-deafness will place the lesion in areas which have been pretty well defined. When the occipital lobe is affected and the visual fibers of the optic tract cut off, a condition of homonymous hemianopsia occurs. "The hemioptic pupillary reaction consists in contraction of the pupil when a ray of light is thrown upon the seeing halves of the retina, while no such reaction occurs when the light is

turned upon the blind halves. It characterizes a lesion of the optic tract."

Ophthalmoscopic examination presents the following conditions as of primary importance in diagnosis: (1) Engorgement of retinal vessels; (2) optic neuritis; (3) retinal hemorrhage; (4) choroidal tubercles; (5) optic atrophy. The first condition exhibits the general vascular state, and a congested fundus, although it might refer only to a local disturbance, hypermetropia, for instance, indicates increased vascular tension. An anæmic appearance signifies the opposite condition. Optic neuritis may be divided into three classes, papillitis (so-called choked disc), retrobulbar neuritis, and simple retinitis. A large percentage of all cases of papillitis is due to cranial tumor, probably about four-fifths. Toxic blood states, as present in lead poisoning and glycosuria, and also in anæmia, chlorosis, and meningitis are causative factors. The ophthalmoscopic findings, in brief, consist in a swelling of stroma and a fulness and tortuosity of the veins. The retina is veiled by a bluish-gray serous deposit. The optic nerve is swollen and projects. The disc margin is indistinct and hemorrhagic spots are present on the retina. Later, the optic nerve takes on a woolly appearance. Glistening white spots encircle the macula lutea or radiate from the center. Retrobulbar neuritis is found in tobacco amblyopia, and a central scotoma exists between the macula and optic nerve. There is discoloration of the disc and usually a spot of atrophy at the outer and lower border.

The neuroretinitis of general toxic conditions occurs in the albuminuria of granular contracted kidney, which is the common condition. The albuminuria of pregnancy must not be forgotten. It is also found in glycosuria. In albuminuric-retinitis the inflamed, red nerve is present, with small arteries, which are accompanied by "silver wire" lines. The veins, where they are crossed, are indented, distally being full and engorged, and proximally, narrowed. Woolly patches are found in stellate groups near the macula lutea or spread in a characteristic fan-like manner. In diabetes the optic nerve does not appear so inflamed and the patches are irregularly arranged. The patches are due to sclerosis and fatty degeneration of the retinal tissue, the peculiar patterns being due to the anatomical arrangement of the stroma.

Arteriosclerotic states are evidenced by tortuosity and irregular bulging of the arteries, with pressure on the veins. Haab considers important, as a diagnostic sign of syphilis, the decrease of retinal arteries with opacities of the walls appearing as fine disseminated scales upon the arteries. It is claimed that other vessel degenerations rarely show this.

Tubercles upon the choroid are, of course, diagnostic of tuberculous meningitis. They may occur singly as a yellow or whitish patch or in groups of several. Their margins, in contradistinction to the atrophic patches of syphilis, are irregular and void of pigment.

Optic atrophy may be primary or secondary. When primary the disc is pale, somewhat bluish-gray in appearance. The vessels are small and apertures in the lamina cribrosa are distinctly visible. Such a condition points to tabes or, in some cases, to general paralysis of the insane. The traumatic factor is to be remembered. Secondary atrophy succeeds neuritis. Here the edge of the disc is irregular, the "silver wire" lines run along the vessels, and the physiological cup is filled in. The possibility of atrophy, disseminated sclerosis, and toxic amblyopia is to be borne in mind.

Summing up the foregoing, I have endeavored to show the inadequacy of diagnostic methods which omit systematic ocular examination, and have entered a plea for a more universal use of the ophthalmoscope. I have outlined the steps in unaided inspection of the eye. Subjective symptomatology has been touched upon. Lastly, the valuable ophthalmoscopic findings have been pointed out in this, an attempt to uplift the veil of possibility overlying an important field in diagnosis.

HYDROCEPHALUS COMPLICATING LABOR.

By G. W. SQUIRES, M.D.,

East Avon, N. Y.

In the fifty-two numbers of the Medical Record of the year 1901, I fail to find an article on the above subject. This has appeared strange to me when almost all known phases of the medical and surgical art is touched upon specifically during a year's publication of the journal. I have also been surprised in looking up the medical literature on this subject to find not a great deal said in even recent publications. An experience with four cases leads me to report the following:

Mrs. D., German, aged twenty-eight years, mother of one living child, was taken with labor November 20, 1902, at 5 o'clock A.M. The previous labor having been long and tedious, there was not thought to be any hurry to summon a doctor. After two hours' labor the mother, believing her child about to be delivered, sent husband for a neighbor, a woman of age and some experience as a midwife. A messenger was also dispatched for the physician who confined the woman with her previous baby. The midwife discovered on examination the child delivered feet first to the neck, and hastily grasping the feet, made traction, hoping to save the child from smothering, but was unable to deliver the head with a pull of all her strength. The family were by this time greatly alarmed, and the doctor not coming, sent hurriedly for me. The other physician was in the house when I arrived. He informed me it was a breech case. He tried to deliver the child by podalic traction. I, in the meantime, anæsthetized the patient by chloroform. The womb being so large, I remarked there must be another baby, but noticing a spina bifida, changed my mind and diagnosed a case of hydrocephalus. The attempt was now made to put on the forceps, but not even one blade could be applied, the head so filled the pelvis. Wearied with failure to apply forceps, the medical attendant returned to traction. Taking hold of the feet with the left hand, with the right applied to the nape of the neck he made very forcible traction. I noticed the neck of the child so attenuated that I expected every second to see the body separate from the head. Suddenly there was a deluge of water accompanied by a gurgling sound, when the doctor almost fell backward with the delivered child in his hands. The placenta was delivered in two minutes, unaccompanied with hemorrhage; there was no perineal rent or lesion of any kind; the mother, within ten days, moved twenty miles away to another village, apparently fully convalescent. On examination of the child, it was found to have had an enormously dilated head that must have contained a gallon of water. There was a great rent of the scalp and membranes parallel with the sagital suture through which the water had escaped before the head was delivered.

SYPHILIS TRANSMITTED BY DENTAL FORCEPS.

By S. S. CARTWRIGHT, M.D.,
ROXBURY, N. Y.

The article by Dr. Farroni, entitled "Syphilis in the Barber Shop," reminds me of a case in which this disease was apparently transmitted by dental forceps. In September, 1897, a young lady called at my office with inflammation of the eyes. It was in the evening; I diagnosed iritis and prescribed atropine instillations and requested her to call the next morning, which she did. I gave her a very careful examination then, and found an eruption on the skin, hair falling out, etc. The history she gave was as follows: While visiting in New York City she had two teeth in the lower jaw extracted by a dentist. This was followed in a few days by swelling, sore throat, and enlargement of the glands of the neck, especially on the side whence the teeth were extracted. There was no question in my mind but that it was a case of syphilis, and the disease commenced in the mouth from the forceps used in extracting the teeth. Treatment by mercury and iodide was successful.

FATAL CASE OF POISONING BY CHLORATE OF POTASSIUM.

By A. R. ELLIS, M.D.,
ROXBURY, N. Y.

Mrs. D. took, on November 9, 1902, about one ounce of chlorate of potassium, which was left for a gargle, supposing it to be rochelle salts. The chlorate and the salts lay on the same shelf wrapped in packages that closely resembled each other. She put the chlorate of potassium in a cup and swallowed it in about half a glass of water. After two hours she began vomiting and purging, when she discovered her mistake. After three days renal symptoms began to manifest themselves, the urine was almost suppressed, and what little was passed was almost black.

Simple diuretics, together with applications of digitalis to the back and about the regions of kidneys and bladder were of no avail. She continued vomiting, the heart grew weaker and the urine remained almost suppressed until November 17, when death relieved her suffering.

General Septic Infection of Nasal Origin.—A. Logan Turner says that the possibility of general septic infection arising from an intranasal lesion may very naturally be overlooked. So insignificant indeed may be the nasal lesion that the patient remains unaware of it, and his physician's attention may possibly be directed to it only accidentally. The author reports three cases, in one of which pulmonary tuberculosis was suspected, in another malaria, and in a third typhoid fever. Some nasal trouble was found in each case, and when this was cured the symptoms disappeared. An intranasal examination should be made in septic conditions of doubtful origin. It is possible, too, that the regular use of the thermometer might reveal more frequently the occurrence of general symptoms in septic conditions of the nasal cavities.—*The Edinburgh Medical Journal.*

Laceration of the Spleen, Laparotomy, Plugging of the Splenic Wounds with Iodoform Gauze; Recovery.—The patient of R. A. Stirling was a boy of fifteen years who was thrown from a horse that placed his foot on the boy's belly. When seen several hours after the boy complained of hypogastric pain and general abdominal tenderness. There was a dulness in both flanks. The abdomen was opened and considerable blood found. Searching for the source revealed a large rent on the posterior border and diaphragmatic surface of the spleen. The wound in the spleen was firmly plugged with iodoform gauze, the end of which was brought out at the upper angle of the abdominal wound. The latter was sutured in the usual way. Two days after the operation the gauze was removed under light anæsthesia, some blood-stained fluid coming away. Recovery was subsequently uneventful, although there was some suppuration at the upper angle of the wound where the gauze had been inserted.—*Intercolonial Medical Journal.*

Gastric Digestion in Jaundice.—S. S. Zimuitsky concludes: (1) That in jaundice, as in all cases of retention of bile in the organism, the gastric function is affected, an hypersecretion being established. This overwork brings about a peculiar condition of the secretory gastric cell—its asthenia. (2) The gastric secretory activity is alike both in acute and in chronic jaundice, *e. g.* when the latter appears in connection with hypertrophic cirrhosis of the liver, provided that no changes in the activity of the secretory gastric cells had occurred previous to the appearance of the jaundice. (3) In chronic jaundice, *e. g.* when it appears in connection with hypertrophic cirrhosis of the liver, there are stages of transition in the activity of the secretory gastric cell from hypersecretion to hyposecretion, the latter sometimes very pronounced. These phenomena are the results of the same condition of the secretory gastric cell, its asthenia appearing only in different degrees and periods. (4) The diminution of the acid secretion of the secretory gastric cells during certain stages of hypertrophic cirrhosis of the liver with jaundice, while the peptic secretion remains the same would tend to prove that the peptic secretory activity of the stomach is of a stronger and more resisting character than its acid secretory activity.—*Russkii Vrotch.*

Neuro-mimesis of Knee Simulating Tuberculous Disease.—Marmaduke Shield reports a case in a woman twenty-six years old. The patient used crutches. Her right lower limb was done up in a Thomas's splint, which had been worn about two years, and the knee was puffy and swollen. Acute pain had been said to follow a local injury. There was, however, no local heat or any obvious thickening of the synovial membrane, yet a diagnosis of tuberculous knee was made. This diagnosis was given up later, when it was realized that the "pulpy" feeling of the synovial membrane was missing. After the splint was removed, and the limb lightly massaged, the swelling, which had been caused by the bandages, disappeared. The adhesions were then broken down under an anæsthetic, both in ankle and knee, and massage continued. Patient now bends knee nearly to right angle, and has commenced to walk.—*The Clinical Journal.*

A Case of Multiple Fibromata Confined to the Internal Plantar Nerve.—Wm. J. Taylor and Wm. G. Spiller report the case of a woman who, for seven years, had suffered from pain and soreness in the sole of the left foot and inner side of the ankle. An operation was performed, and thirteen small tumors were removed from along the line of the distribution of the internal plantar nerve. They varied in size from that of a hickory nut down to a very small pea. Two years later two tumors were removed, one at the instep and one at the ball of the great toe. Seven years afterward six tumors of the same general character were removed from the same region. They were found to be pseudoneuromata. In another ten years five small tumors were removed, and one the size of a walnut was found to be attached to the internal plantar nerve at several joints by rather long bands, apparently of nerve tissue. About five inches of the nerve were removed, the wound healed, and for the first time in fourteen years the patient was free from pain. Since that time she has been perfectly well.—*The Journal of Nervous and Mental Disease.*

PROFESSIONAL SERVICES TO EACH OTHER.

RALPH WALDO EMERSON, in his masterly essay on compensation, makes his earnest and thoughtful reader understand that nothing good in the world is to be obtained without its equivalent drawback of pay for services received. The loan of fortune means the pound of flesh for the creditor. When the desired result is obtained it is always a question between the game and the candle. The contemplation of relative conditions evens up all things in a very general, if not always a very satisfactory, way.

It would be strange, indeed, if the law did not apply to the medical man in his efforts to succeed along the different lines of his arduous labors. Often enough the bread he seeks comes to him in plenty when his teeth are gone and his taste has palled. Even the so-called pleasure of the work for the work's sake makes him conscious of the sweat on the brow and the tug at the bit. Where much is required much must be given. The man who is struggling for a reputation with its accompanying emoluments must pay for it as he goes along. It is impliedly granted that he owes something to his fellows as well as himself, and not infrequently he discovers that his own claims are not by any means foremost. Thus it happens that the man who is bent on obtaining extra skill in different directions of human endeavor must always consider those who are ready to use him. It is the compliment of being asked to do the thing that balances the obligation of having it done. We wish to apply these remarks to the good and the bad side of those time-honored reciprocal professional attention that apply to sick doctors and their families.

It has often been said, and with some show of truth, that the professional courtesies in question have become so much strained that the poor, sick physician, or his equally helpless wife, is generally worse off for willing continuous and systematic treatment than most free patients who come under the doctor's care.

There are many reasons why the physician is incompetent to attend to himself when sick or to any of his family in like condition. It has consequently been a time-honored custom, glorious in its graciousness to help him in his time of need. The reciprocation of such services has been the obligation of true friendship, and the willing helpfulness of a brother doctor was even more blessed to give than to receive.

While we must acknowledge that the same laudable spirit still exists to give us support and comfort in our most trying hours, we must at the same time admit that it is in danger of dying out in consequence of the abuses which the fashions of the day make possible. The trouble seems to be that most of the time of the general consultants and specialists is taken up with many medical brethren who have no direct claim on their friendly aid save that of belonging to the same profession, and who have no means of exchanging services of equivalent value. It goes without saying that these gentlemen are very much imposed upon in many ways, and feel, by virtue of their position, that they are doing more than their share of purely friendly professional service.

Each applicant may believe he has a claim on the special skill of his brother worker, but he apparently forgets that he is only one of a crowd which is proportionate to the fame of the man who is supposed to receive all with becoming courtesy and responsive concern. These are certainly matters to think about in view of striking a reasonable balance for both sides of the equation. The exactions of time and service appear to be based on technical grounds, rather than on purely friendly obligations. We can hardly blame such as are imposed upon in this respect for now and then believing that the extra burdens imposed are oftentimes heavy ones and somewhat grievous to be borne. In some respects it must be admitted that we have outgrown our ancient privileges. Instead of distributing them, as formerly, among personal friends, who are always glad to serve us, we are concentrating the work on a comparatively few, who are bearing more than their share. From a purely business point of view it would seem only equitable and right that some equivalent should be given for time consumed. This may sound a trifle heretical, but the reasonable adoption of such a principle would very effectually remedy a growing evil. It is not difficult to see—by every one who views the subject with absolute impartiality—that it would be much better to make some pecuniary standard for professional services to each other than to trust to present methods. Personal friendship in this matter is one thing, but mere professional etiquette is quite another thing. The etiquette is sentimental and the fee, however small, is practical. Besides there is an equivalent of some sort to balance properly the implied rights of each party in the transaction. It is a grave question whether we shall not sooner or later come to this common-sense method of equitable adjustment of material obligations. Then at least the sick doctor or the doctor's wife need not hesitate to think whether or not it may be proper to make a choice of a particular attendant, and need not fear to place himself or herself under obligation in so doing.

THE ABSURD ARGUMENTS IN FAVOR OF SUBSTITUTION IN MEDICINES.

THE attitude of the retail druggist in opposition to the Bostwick bill against substitution, as disclosed at the hearing before Governor Odell, was the subject of discussion at a stated meeting of the Society of Medical Jurisprudence on Wednesday evening. As appears in the report of the proceedings made to the society, the druggists were represented by a body formidable in number and

in behalf of the various associations. Objections were strenuously and insistently urged upon the Governor by many speakers that the enactment of this bill would prevent the pharmacist from consulting his own convenience in dispensing one make or brand which he might have, in place of a specified other product which he might not have in stock. The great hardship of this Bostwick bill, in view of the large number of manufacturing chemists making officinal products all alike, of the same formula, etc., was enlarged upon, the druggists claiming the right to exercise their own discretion and convenience; the convenience of the patient in such exigencies was equally sacrificed. Again, a patient departing for the country, or for any reason requiring a larger quantity of medicine than that ordered in the physician's prescription, could not be accommodated without the commission of a misdemeanor; nor could the patient be protected from the mistakes and incapacities (much enlarged upon) of the physician to write proper prescriptions, for the reason that this bill would prohibit the druggist from exercising his discretion in the premises. It would even prohibit him from adding an excipient in making a pill or suppository.

This claim of the druggist to an inherent right to consider his own convenience must certainly be regarded as a startling, not to say astounding, proposition. There could be no more false nor misleading statement than this—that the pharmacopœia products are of a uniform quality. Every physician knows that the personal equation counts here to a very large and important degree, as it does in everything else. The most ordinary, simple galenical preparations differ in even obvious physical characteristics as produced by different pharmacists, but the doctor is accustomed to dealing with, and adapting his practice to, these conditions. He does not, as a rule, specify largely, carelessly or indifferently, or to any ordinary extent,the source from which ordinary officinal agents must be dispensed; he does very properly and necessarily, and to the best interests of pharmacy, medicine, and his patients, specify particular products which are well-known to be of recognized and proved standard of excellence and uniformity, and for reasons and under conditions in which he is, and must be the sole judge and authority. There are some officinal preparations which it is devoutly to be wished could be made by manufacturing chemists; let us take so simple a thing as an infusion of digitalis; has not the convenience of the druggist caused this to be made from a fluid extract and hot water? Character, ability, enterprise, and skill find as beneficent a field in competition in articles of pharmaceutical standard as in other products of commerce. A special preparation of ergot, opium, or ether is none the less such because the pharmacopœia defines a standard of formula or quality.

The druggist will concede, we believe, that even the doctor knows that the written injunction "fiat pil" conveys the direction that the druggist shall use the excipient or vehicle necessary by officinal requirements or by technical practice; yet these timorous druggists expressed great concern lest they should commit a misdemeanor in doing so.

Similarly specious is the assumption that in dealing with erroneous prescriptions the druggist is restrained or interfered with or prohibited in any way from the exercise of his professional vigilance and discretion, both as regards the doctor and the patient. The druggist must always stand in these respects in precisely the same position as he does now. It is absurd, as claimed in behalf of the druggist, that in calling attention to error he would incur the mortal enmity of a physician; ordinary discretion and tact, dictated by professional comity, are necessarily to be expected, and must impress alike favorably both the patient and the physician.

Whilst it might be conceded that there are druggists whose "convenience" might not be divorced from the highest considerations for the patient's welfare, the physician cannot for a moment recognize or submit to the stand taken by the druggists as ground for requesting the Governor to withhold his signature from the Bostwick bill—the stand taken by them in these matters. It was the generally expressed feeling at the meeting of the Society of Medical Jurisprudence that the attitude of the druggists was neither judicious, convincing, nor sincere, and we emphatically concur in this opinoin; also in the confidence expressed that the Governor would approve this bill brought about in the public interests by the flagrance of malpractice in pharmacy.

If anything were wanting to convince the Governor of the gravity of the situation in the public interests, it would be the very illuminating disclosures made before him of the facts that the present laws *do not deter* substitution, and that the Bostwick bill is found at fault only in that it makes no loophole for this offense, and is well designed to discourage its practice. That it imposes no restraint nor penalty nor hindrance upon the druggist in the exercise of every proper function and right, must be the opinion of all candid people conversant with the subject. There is no ground upon which the druggist should enjoy immunity from the common obligations which obtain in ordinary commercial dealings; whilst, on the contrary, it is very evident that he is under obligations peculiarly imposed and inherent in the very nature of his calling.

The Bostwick bill will be welcomed as a measure wholly in the right direction, and the Governor has an opportunity to confer a great public service in giving it his approval.

The Pathology of Acute Rheumatoid Arthritis.

The grouping under one heading the diseased conditions now called arthritis deformans, osteoarthritis, and rheumatoid arthritis is believed by many writers to be erroneous, and it is thought that these terms include two or more separate diseases. Dr. W. Hale White, physician to Guy's Hospital, writes in the reports of that institution, Vol. 52, on two cases of acute rheumatoid arthritis which have recently been under his care, and the differences which he observed on the one hand between this acute condition and rheumatic fever, and on the other hand between the same and other forms of the disease comprehended under the three terms, arthritis deformans, osteoarthritis, and rheumatoid arthritis. Dr. A. E. Garrod and Dr. G. A. Bannatyne wrote respectively in the *British Medical Journal*, Vol. 2, 1901, and in the *Practitioner*, May, 1900, on the subject, stating that they were much

struck by the differences between the acute cases and other patients said to be suffering from rheumatoid arthritis. Dr. Bannatyne was the first to insist that the acute form of rheumatoid arthritis was a separate disease, and Dr. Garrod, in opening the discussion on "Chronic Diseases of Joints Commonly Included in the Terms Chronic Rheumatism, Osteo-arthritis, and Rheumatic Gout," at the meeting of the British Medical Association in 1901, said, speaking of the acute form, "Our knowledge of the morbid anatomy of this disease is very scanty. It has so little fatal tendency in its earlier stages that opportunities for examining such joints post-mortem are very rare. In our London hospitals such opportunities are practically wanting, and I believe that we could have no more valuable contribution to this discussion than a careful description of the post-mortem appearances of an early stage of this kind of rheumatoid arthritis." Dr. W. Hale White has been able to supply the needed description, and has published an account of a post-mortem on a patient who had the disease, which further proved to his satisfaction that acute rheumatoid arthritis is a separate disease..

The malady, as demonstrated by the post-mortem, is essentially one of the synovial membrane and the soft tissues around the joint, the very slight change in the cartilage and bone being apparently secondary to that of the synovial membrane. "Probably," says Dr. White, "the disease is of microbic origin; a diplococcus was found in my case and other observers have found microorganisms, but the specific micro-organism has not yet been certainly isolated. The pathological changes shown by the post-mortem consisted of a chronic inflammation of the synovial membrane, together with a thickening of the tissues outside the joint. The pitting of the cartilage was slight and secondary to the changes in the synovial membrane. The cartilage itself was healthy, and the affection of the bone was slight and due to perforation of the cartilage by the thickened synovial membrane. There were no bony or cartilaginous growths.

A description is also given by Dr. White of the clinical features of another patient under his care suffering from acute rheumatoid arthritis, who is still alive. Radiographs were taken of the case which died, and of the one living, from a consideration of which the writer suggests that the exceptional transparency of bone observed may some day be found to be one of the distinctions of acute rheumatoid arthritis from other diseases having a similar name.

Observations upon Leprosy Occurring in Japan, Iceland, and Norway.

Dr. Judson Daland of Philadelphia read a paper on the above subject before the Philadelphia County Medical Society, January 14, 1903. It appears that all the islands of Japan, with the exception of Yezo, are infected with leprosy, The official report states that there are 10,000 cases of leprosy in Japan but Baelz believes that there are from 30,000 to 50,000, while Souton estimates the number at 23,660. The disease is considered to be contagious by both the inhabitants and the physicians, and precautions are taken to prevent close personal contact between lepers and the general population. Dr. Baelz of Tokyo, utilizing the fact that perspiration does not occur in the area of the skin involved in leprosy, has devised an ingenious method of outlining the parts affected by rubbing aniline over the suspected area and then injecting pilocarpine. The sweat thus produced dissolves the aniline and stains and outlines the area of normal skin, while abnormal skin remains unstained. He takes the view that leprosy is contagious in but a slight degree, and despite his wide experience, has never observed a single instance of transmission of the disease. He further believes that certain cases recover spontaneously and that others are favorably influenced by rubbing the diseased area of the skin with pumice-stone until blood appears, and then applying a 20-per-cent. salicylic acid lanolin-vaselin ointment. In addition ½-gram capsules of oleum gynocardia are to be taken thrice daily after meals. Every fourth day an additional capsule is to be given until ten capsules are taken thrice daily. This treatment should be continued for not less than one year.

Iceland, with a population of 70,000, contains, it is believed, 200 lepers. The inhabitants maintain that leprosy is non-contagious. Statistics show that heredity plays an etiological rôle, that the tuberculous variety is the most common, and that more females are afflicted than in India, where the proportion is but one female to four males. Dr. Daland is not in accord with the popular opinion entertained in Iceland that the disease is slowly diminishing, for the reason that it is impossible to obtain accurate information regarding the number of cases existing in Iceland, not only in the past, but also in the present.

Norway is the only European country in which leprosy is endemic, but owing—the writer thinks—to the enforcement of segregation, the disease is rapidly disappearing. The Norwegian physicians are uncertain as to the contagiousness of leprosy, although the majority, including Hansen, hold that such is the case. In Norway both sexes suffer about equally from leprosy. In 1882 107 cases were reported cured during twenty-five years. Hansen is of the opinion that the bacillus may enter the body through wounds in the skin, and that infected clothing may spread the disease. Arning of Hamburg and Ehler of Iceland hold similar views.

The Prevalence of Bilharziosis in Egypt.

Mr. Frank Milton, Professor of Clinical Surgery at the Government School of Medicine and Surgery, and surgeon to the Kasr-el-aim hospital at Cairo, writes, in the *Lancet* of March 28, on this disease. "Bilharziosis," he says, "develps in two distinct ways. It may cause the destruction of the mucous membrane of the part which it attacks by the formation of a new fibrous tissue replacing the glandular elements of the part, this being the atrophic form, or it may cause great overgrowth of the normal elements of the part attacked with the formation of polypi and similar outgrowths, this constituting the hypertrophic form; or these two forms may be combined to bring about a variety partaking of the characteristics of the two, with the formation of an enormous mass of tissue *sui generis*, which may be called bilharzia tissue. The malady is extremely prevalent in Egypt, and was discussed fully at the recent medical congress held at Cairo. According to Mr. Milton, all ages are liable to be attacked by the disease, the records showing three cases of children aged four years with bilharziosis of the bladder, and nineteen patients over sixty years of age. By far the largest number are between the ages of fifteen and forty-five years. The vast majority of cases occur among males. As regards race, a very marked difference is found. Of 925 patients which came under Mr. Milton's observation at the Cairo hospital, 908, or nearly 98 per cent., were Egyptians, the remainder being made up of six Berberines, six Copts, and only five Soudanese. The small number of Copts and Berberines may be accounted for by

these being essentially indoor or town races, but the markedly small number of Soudanese can hardly thus be accounted for; it must be remembered that a large number of these blacks have passed the greater part of their lives in Egypt and under the same conditions as the native Egyptians. Nearly all the sufferers from the disease were of the peasant class. The most common form of the disease as seen at the hospital, is bilharziosis of the bladder, of which there were 599 cases, or 64 per cent. of the whole number treated; the next most frequent form was what is almost the same form of the disease, viz., vesical calculus, of which there were 134 cases; after this, urinary fistulæ, 113 cases; and then bilharziosis of the rectum and general bilharziosis, 53 cases.

Malaria and Agriculture.

An excellent contribution to the above subject is made by Prof. Glenn W. Herrick of the Agricultural College, Miss., in the April number of the *Popular Science Monthly*. The public at large have hitherto failed to appreciate at its full significance the immense influence which malaria exerts upon agriculture. In Italy, for instance, Celli shows that the mean mortality statistics give about 15,000 deaths yearly from malaria. He further says that, "calculating from the number of deaths the number of patients, we arrive approximately at about two million cases a year."

"The loss of labor and of production, and the expenses entailed in dealing with this disease consequently amount to several million of francs." About five million acres of land uncultivated, or improperly cultivated, which represents an enormous loss. One railway company spends on account of malaria one million fifty thousand francs ($200,000) a year. He sums up by saying: "One can positively assert that malaria annually costs Italy incalculable treasure."

Professor Herrick points out that malaria affects agriculture injuriously, in unfitting men for long or energetic hours of labor. The disease saps their vitality so thoroughly, that they are unable to do efficient work, and consequently in those districts in which malaria is rife, the soil is not cultivated properly, and its inhabitants do not contribute their just quota as wealth producers.

So far as the Southern States of this country are concerned, the following figures taken from the last census will give a fairly good idea of the evil wrought by malaria. Number of deaths for year ending May 31, 1900:

	Total	Consumption	Heart Disease	Pneumonia	Typhoid	Dysentery	Malaria
Louisiana	20,955	2,016	1,149	1,045	1,077	385	1,030
Mississippi	20,251	2,129	876	2,168	1,370	380	983
Alabama	25,609	2,666	1,111	2,450	1,713	864	1,005
Georgia	26,941	2,651	1,350	2,598	1,585	781	1,011
S. Carolina	17,166	2,133	843	1,324	970	578	479

Taking, therefore, Celli's basis of estimate, it will be found that in the five States mentioned there were, approximately, 635,000 cases of malaria in the year ending May 31, 1900. From the foregoing facts and deductions the writer draws the conclusion that malaria is responsible for more sickness among the white population of the South than any disease to which it is now subject.

Professor Herrick gives as a striking example of a concrete effect of malaria upon agriculture, the Delta of the Mississippi, one of the most fertile regions of the world. The land magnificently adapted for producing grain, vegetables, cotton, and fruit in almost unlimited quantities is comparatively unsettled and a drug in the market on account of the prevalence of malaria. Malaria is the chief bane of tropical or semi-tropical countries, and, according to Nanson, causes more deaths and more disposition to death by inducing cachetic states, predisposing to other affections than all the other parasites affecting mankind together..

Professor Herrick will have done yeoman service for his country if his article should give use to energetic efforts to stamp out malaria in the Southern States. The way has been indicated by Ross, Nanson, and the Italian investigators, and at the present time in Italy and in various parts of the British Tropical Empire, a strenuous crusade is being undertaken against the malaria-bearing mosquito. Surely, then, the United States, with its wonderful resources of wealth and brains, should not be backward in endeavoring to stamp out the disease within its own borders, but should rather be in the van in demonstrating that it is possible to rid mankind of one of the greatest menaces to health and obstacles to material progress.

News of the Week.

Prof. Hermann Tillman of Leipzig University is on a brief visit to America for recreation and has been the recipient of many professional courtesies during his short sojourn in this city. He is the guest of Prof. Carl Beck, who tendered him a complimentary dinner immediately after his arrival on Friday, May 8. Among the guests were Drs. W. T. Bull, R. Abbe, George R. Fowler, W. B. Coley, C. A. Von Ramdohr, and C. Pfister. Prof. Tillman visited the New York Hospital and the St. Mark's Hospital the day following, and afterward attended a lecture at the Post-Graduate Hospital, given by Professor Beck, and gave a brief address.

On Sunday evening he was given a dinner by Prof. W. T. Bull at the University Club, at which were present Drs. L. A. Stimson, Carl Beck, A. G. Gerster, George F. Shrady, B. Farquar Curtis, C. A. Von Ramdohr, C. Pfister, Willy Meyer, F. H. Markoe, and John B. Walker. At the reception which followed, there were present: Drs. Maurice H. Richardson (of Boston), Robert Abbe, Mr. Moynihan (of Leeds, England), Drs. Frederick S. Dennis, J. A. Blake, George E. Brewer, Howard Lillienthal, John Rogers, Jr., William B. Coley, F. Kammerer, Walton Martin, E. H. Pool, Carlton Flint, Lucius W. Hotchkiss, E. Eliot, Jr., R. G. Wiener, Charles N. Dowd, Bern B. Gallaudet, Milton Foote, Arthur L. Fisk, J. Hilton Waterman, S. E. Sprague, Wisner R. Townsend, Royal Whitman, Duff Bullard, M. P. Denton, Joseph Wiener, Jr., B. T. Tilton, and Percy R. Tunure.

On Monday Professor Tillman visited the Roosevelt Hospital and then left for Washington, D. C., to attend the Congress of the American Physicians.

Barber's Bill Vetoed.—Governor Odell has decided not to sign Senator McEwan's bill providing for the licensing of barbers and the inspection of shops. The Governor regards the bill as too drastic, and as not meeting the situation which it was designed to meet. He is of the opinion that to compel the licensing of every apprentice and to make the new men subject to sanitary restrictions, without including all barbers and shops, would not effect the desired object. If any are to be examined, all should be examined.

Several Bills Relating to Medicine Signed.—Governor Odell signed, on May 11, a number of bills, among which were some dealing with medical matters. These were as follows: Mr. Roger's bill appropriating $570,000 for repairs and improvements to the State insane hospitals.

Mr. Hughes's bill appropriating $50,000 for the

purchase of a site for a new State hospital for the insane in the northeastern part of the State north of Rensselaer County.

Mr. Hammond's bill appropriating $3,700 for improvements to the Syracuse Institution for Feebleminded Children.

Mr. Graeff's bill appropriating $115,000 for the construction of the State Consumptive Hospital at Ray Brook, Essex County.

Mr. Sherry's bill making it a misdemeanor to distribute samples of drugs or patent medic nes in such a way that children may get at them.

Mr. Wainwright's bill authorizing New Rochelle to appropriate $2,500 annually to the New Rochelle Hospital.

Senator Ambler's "Pure Food Bill," prohibiting the adulteration of food, confectionery, and condiments.

Bequests to Hospitals.—By the will of the late Hiram Brooke of Philadelphia bequests were made to hospitals as follows: Pennsylvania Hospital, German Hospital, Hahnemann Hospital, Jefferson Hospital, Episcopal Hospital, Bethany Dispensary, each $2,000; St. Joseph's Hospital, Insane Department of the Pennsylvania Hospital, Jewish Hospital, each $1,000; St .Timothy's Hospital; Home for Consumptives at Chestnut Hill, Philadelphia Dispensary, each $500.

New Rules for Dealing with Garbage.—Commissioner Woodbury has drawn up new rules, with regard to the separation of garbage. Department employees have visited every building in the city where garbage is collected, and have distributed cards bearing these rules. According to the new rules, refuse will be divided into three classes, as follows: matter put into garbage receptacles, matter put into ash receptacles, and matter put into rubbish bundles. The new rules are explicit and will be strictly enforced. Another rule also will be enforced forbidding the use of leaky receptacles for putting out garbage coming under the first head, and a second rule forbidding any kind of refuse matter from being thrown into the street. The new rules are said to be the forerunners of an ultimate plan making the city's garbage yield the greatest commercial return, as an actual asset of the department having charge of the collection. Dr. Woodbury will, indeed, have deserved well of the community if he can thoroughly reorganize the system of garbage collection in this city. The manner in which the work is done at present is faulty and slipshod in the extreme, and would not be tolerated in any large European city.

Smallpox at Manila.—It is reported from Manila, that smallpox has broken out among the men of the Second Infantry aboard the transport *Sheridan*. The vessel will be quarantined for five days. It is said that the health officers will reimpose the quarantine regulations of 1902, owing to the fear of a slight increase in the spread of cholera.

Set-back for Temperance.—Temperance would certainly appear to be losing ground in this country. In the past three months of 1903, Vermont, which has staunchly upheld prohibition since 1852, has backslidden; New Hampshire, a prohibition State for forty-seven years, has decided to abandon this principle. North Dakota, which adopted prohibition as a part of its Constitution, will, it is said, through the next Bismarck Legislature, submit an amendment to abolish it entirely. In Kansas the cause of prohibition languishes.

United States Delegates for the Red Cross Geneva Convention.—The delegates chosen to represent the American branch of the Red Cross organization, at the International Red Cross Convention, to be held in Geneva next September, are: F. B. Loomis, First Assistant-Secretary of State; General G. B. Davis, Judge Advocate-General of the Army, and Commander Nathan Sargent, U.S.N. Miss Clara Barton has not been selected as a delegate, which is believed by some to be intended by President Roosevelt as a mark of his displeasure. The three chosen ones are said to be in sympathy with the Washington malcontents, who advocate a thorough reorganization of the Red Cross Society in this country. The forthcoming convention in Geneva will deal with some very important matters relating to the work of the Red Cross Society. It will, for instance, be proposed in the amendments to provide for a careful examination of bodies on the field prior to their inhumation or incineration, to obviate the chances of men being buried alive after a battle. It will also be proposed that a clause shall be added to the international treaty, providing that every officer or soldier shall bear upon his person a mark rendering it easily possible to establish his identity. The suggestion, too, has been put forward that field hospitals and other temporary establishments, following troops on the field of battle to receive the sick and wounded, shall be considered neutral under all circumstances, and that if they fall into the hands of the enemy it shall be a duty to return them to their army when they are no longer required for the care of the sick. The question will also be discussed as to whether there is substantial reason for retaining as the sole distinctive sign a red cross on a white field, or whether it would be proper to allow exceptions in the case of non-Christian countries, such as Turkey, which has substituted a red crescent for the red cross.

Situation Decided upon for the Camp for Consumptives.—The President of the New York Board of Health has decided to place the tuberculosis camp on North Brother Island. The opposition encountered up the State in the attempt to secure a site has been so great that it was found necessary to abandon the plan.

Newsboys' Homes.—At the first session of the conference of the National Congress of Mothers, held in Detroit on May 6, Mrs. Florence Kelley of New York read the report of the Committee on Child Labor. She said the State of Pennsylvania—in particular the cities of Philadelphia and Scranton—is the worst in the Union in regard to employing children in the night. In her report on the employment of children in the streets, such as the newsboys and bootblacks of the large cities, Mrs. Kelley said these young ones received little or no assistance from the newsboys' and bootblacks' homes. These institutions, she declared, devoted much time to looking after the transient foreign element, and the newsboys, bootblacks, and telegraph messengers found relief only in the juvenile courts and the Catholic protectorates.

Smallpox on Board a Vessel in the Bay.—The British bark *Baldwin* arrived at New York on May 8. Two of her crew had smallpox on the voyage, and she was detained at quarantine for disinfection. The first case was contracted at Port Spain, Trinidad, and another case developed later.

Utilizing City Refuse.—Dr. Woodbury, the Street Cleaning Commissioner, is undertaking an experiment with the view of making use of, as well as getting rid of, the city refuse. The Commissioner has started an incinerating plant, for the purpose of destroying refuse and of developing motive power. The experiments are being carried on in a dismantled old school-house at North Moore and Varick

streets. The tests—which have been made under unfavorable circumstances as regards plant—have so far proved that every half a cubic yard of waste burned is capable of evaporating thirty-two pounds, equal to the production of one-horse power. The absence of garbage and the completeness of the combustion prevent unpleasant odors. Dr. Woodbury intends either to sell the rubbish as fuel or to convert it into heat. Shoreditch, a district in the East end of London, was the first place in which a like experiment was tried, and it has been a fair success. The city of Bradford, in England, is lighted by means of electricity obtained by burning refuse.

Illinois Convict Labor Law.—The Illinois Convict labor bill, which passed both branches of the General Assembly without any opposition, becomes effective on July 1, 1904. It abolishes contract labor, and provides for the employment of convicts not to exceed eight hours a day in the manufacture of articles used by the State. It is to all intents and purposes a duplicate of the measure recommended by the National Industrial Commission.

Strike of Smallpox Guards.—At Landsford, Pa., a most remarkable strike has occurred. The guards at some houses which are in quarantine, on account of smallpox, went on strike, because the Board of Health refused to increase their wages from $2.50 to $3.00 per day. The guards deserted their post. When the Board of Health heard of the state of affairs, a meeting was called, and it was resolved to capitulate without arbitration. The guards received the increase demanded.

Death from Typhoid Fever at Stanford University.—Foster Ely Brackett, a son of Dr. John E. Brackett, retired army surgeon, now living in Washington, died of typhoid fever at Stanford University on May 10.

Charter Refused Christian Scientists.—The Supreme Court of the State of Pennsylvania has just rendered a decision upholding the refusal of the lower court to grant a charter to the First Church of Christ, Scientist, as injurious to the community.

College of Physicians of Philadelphia.—At a stated meeting, held May 7, Drs. David L. Edsall and Ralph S. Lavenson presented a communication entitled "Concerning the Nature of Chronic Progressive Polyarthritis." They reported the results of observations upon a number of cases in which injections of tuberculin had been made with a view to determining whether the joint-lesions were, as had been suggested, tuberculous in character. In a number of cases there was elevation of temperature, and, in one case especially, also swelling of several joints. In this case acid-fast bacilli, conforming morphologically with tubercle-bacilli, were discovered in an emulsion of glands excised from the neck, although the results of inoculation of guinea-pigs were negative. Dr. S. Weir Mitchell read a paper entitled "The Relation of Headache to Storm Conditions." He referred to previous observations showing the relation between traumatic neuralgia and also migrainous neuralgia and storm conditions, and he reported the case of a man who had kept for seven years a careful record of the attacks of migraine from which he suffered. When the attacks were charted month for month a distinct correspondence was noted between the number of attacks of headache and the prevalence of storm conditions.

Insanitary Washington.—The insanitary conditions which prevail in many portions of Washington, is the subject of a forcible article which appeared in the *New York Tribune* Illustrated Supplement on May 3. The capital of the United States is rightfully regarded, in many respects, as one of the most beautiful cities in the world, and it comes therefore as somewhat of a shock to hear that a large number of its inhabitants exist under more disgusting and disgraceful conditions than are present in the slums of Whitechapel, London, or in the tenement district of New York. That such is the case is vouched for, however, by experienced and reliable observers, and these assertions are borne out by the statistics of health of Washington. The health report for 1901 shows that out of every thousand colored children born 457 died in the first year. In other words, nearly every other colored baby falls a victim to the insanitary conditions within twelve months after birth. For white children the rate is very different, the figures for the same period showing a mortality of 187 to the thousand among white babies in the first year. Now the figures of the alley population have direct bearing on this death rate. The total alley population, according to the last report of the Metropolitan Police Department of the district, was 18,978, of whom only 2,150 were white persons. Alleys then play a significant part in the health history of the national capital. The alleys, however, are not the only parts of Washington which breed disease, and the whole matter is well and fully discussed in the article referred to.

Christian Scientists Lose.—It was decided, in the Supreme Court on May 4, that the "First Church of Christ, Scientist," is not deserving of a charter in Pennsylvania. Justice Potter, who delivered the opinion, upholds the late Judge Arnold and ex-Judge Dimner Beeber, the referee to whom the application for a charter had been referred.

The Fluorescence of Quinine and Other Remedies in the Cure of Malarial Fever.—In our issue of April 18, in referring to an article by Dr. A. F. A. King, Washington, D. C., on "Quinine and Malaria," an error was perpetrated. Dr. King was made to infer that the parasite of malaria scarcely ever develops except in darkness, whereas the idea upon which he founds his theory of the fluorescence of quinine, being the cause of its destructive action upon the malarial parasite, is based upon the view that the parasite does not sporulate in the dark. In the near future Dr. King's theory will be treated at some length in our pages.

Miss Gillette Reappointed.—Governor Odell has reappointed Miss Grace Gillette, the present Secretary of the Board of Visitation of Manhattan State hospitals.

Absent-treatment Healers in Court.—A suit was brought a short time ago by the American School of Magnetic Healing of Nevada, Mo., against C. M. Bishop and the *St. Louis Christian Advance*, for libels published in that paper. In the article to which objection was made the "healers" were referred to as charlatans. The plaintiffs claimed $20,000 damages, but the Court awarded them $750. The case was then carried to the Missouri Supreme Court, which reversed this decision and gave judgment for the newspaper editor. In its opinion the Court said, that while the contest between the different schools of medicine must of necessity go on, it must go on within limits of reason, but when supernatural powers were claimed, even if proved by witnesses who had benefited, "we are not required to believe it." The School of Magnetic Healing has appealed to the Supreme Court.

Leprosy and Fish.—Mr. Jonathan Hutchinson, F.R.S., has returned to England after a lengthy

investigation in India into the causes of leprosy, Mr. Hutchinson has been known for years as the foremost exponent of the hypothesis that the chief origin of leprosy is the consumption of fish. He visited, while in the far East, Colombo, Madras, Lahore, Calcutta, and Bombay, at which places he held public meetings and discussions. Mr. Hutchinson also went to the leper asylums at Colombo, Madras, Calcutta, Purula, Asousal, Agra, Tarutaran Jullundur, and Bombay. The evidence collected was not by any means convincing in favor of the fish-eating theory of the causation of leprosy. In Madras and Calcutta all the lepers with but one exception denied ever having eaten fish, while at Purula, of the 500 inmates of its asylum, all had been habitual fish eaters.

The prevalence of the disease in India is no greater than in Norway. In Ceylon, where scarcely any fish are eaten, the incidence of leprosy is less than two per 10,000. In Mimcoy, where fish is the main article of diet, the percentage is 150 in 10,000. In Bombay Asylum, which contains 400 patients, all were fish eaters.

College of Physicians of Philadelphia—Section on General Medicine.—At a stated meeting, held April 13, Dr. Augustus A. Eshner exhibited a case of cyanosis of the extremities. The patient was a man, seventy-two years old, who presented cyanosis of hands, feet, and nose, greater on the left side, with greatly diminished pulsation in the left radial artery and absence of pulsation in the dorsal artery of the left foot. The heart was arrhythmic at times, and there were signs of chronic bronchitis. The accessible vessels were soft, and there was no evidence of obliterative arteritis. The cyanosis was thought to be due to vasomotor atonicity and to represent the paretic type of vasomotor ataxia. Dr. David Riesman exhibited a case of cervical rib. The patient was a middle-aged woman presenting symptoms of pulmonary tuberculosis, but in whom there was found, on palpation and radiographic examination, a rudimentary cervical rib on the left side and a much more fully developed cervical rib on the right side. Dr. J. M. Anders reported two cases of typhoid fever, one complicated by perforation and the other with hemorrhage simulating perforation. In the first case the condition was discovered only on post-mortem examination, and consisted in an exceedingly small perforation, together with the lesions of peritonitis. In the second case operation was performed and no perforation found, but hemorrhage was at this time suspected. Dr. J. C. Wilson reported a case of sarcoma cutis, of tissue. The patient was a young woman in whom the condition developed in the sequence of injury to a mole that had long been present on the forehead. The case was remarkable for the large number of secondary growths and the rapidity with which they formed. Dr. D. Riesman made some remarks on palpation. He has found that in the teaching of students and in practical experience excellent results were obtained in practising palpation by applying the ulnar border of the hand in the intercostal spaces in the same way as the finger is applied in the practice of percussion. Dr. Alfred Stengel presented a communication entitled "Syphilis of the Lung Simulating Phthisis." He pointed out how syphilis might involve the lungs in the form of gummata, of interstitial connective-tissue hyperplasia, of parenchymatous changes, or of ulceration and destruction, and he reported a case in which he had found on post-mortem examination the lesions of gumma of the lungs, and another in which improvement quite to the point of recovery had taken place under antisyphilitic medication.

Segregation of the Insane.—On Saturday morning, May 9, the National Conference of Charities and Corrections, being held at Atlanta, Ga., discussed the subject of "Colonies for the Segregation of Defectives." A committee report was submitted by Alexander Johnson of Fort Wayne, Ind., and a general discussion upon matters relating to the segregation of the feeble .

Obituary Notes.—Dr. Robert N. Hartman, professor of analytical chemistry in the Colorado State School of Mines at Golden, was suffocated in the gas-generating room on May 8. Professor Hartman was born at Ghent, N. Y., in 1872. He was graduated from Chambersburg Academy in 1887; from Pennsylvania College in 1891, and from Johns Hopkins in 1894. He came to Golden in 1899.

Dr. Rufus Ogden Mason died at his home, 348 West Fifty-eighth street, on May 11, aged seventy-two years. The deceased physician was born in Sullivan, N. H., and was graduated from Dartmouth College in 1854, with the degree of A.M., and from the College of Physicians and Surgeons in New York in 1859. He served as an Acting Assistant Surgeon during the Civil War. Dr. Mason was an author and a somewhat voluminous writer, some of his books are: "Sketches and Impressions, Musical, Theatrical and Social, Including a Sketch of the Philharmonic Society of New York," 1887; "Telepathy and Subliminal Self," 1897; "Hypnotism and Suggestion in Therapeutics," 1901.

Dr. Dwight S. Chamberlain, President of the Lyons National Bank, died of pneumonia at Lyons, N. Y., aged sixty-five years. During the Civil War he was a surgeon in the Ninth Heavy Artillery and was afterward in charge of the Soldiers' Hospital of Syracuse.

Dr. Archibald Taylor of New York City died at Somerville, N. J., on May 12, of pulmonary tuberculosis, aged forty-two years.

Dr. Samuel G. Dearborn of Nashua, N. H., died on May 8, of septicæmia, aged seventy-six years. He was born at Northfield, N. H., and was descended from an old colonial family, remarkable for the number of its physicians.

Dr. William Johnstone, a well-known physician of Washington, and formerly of Birmingham, England, died at Washington, on May 7, aged fifty years.

Dr. Edward Martin has been appointed by Mayor Weaver Director of the Department of Public Health and Charities recently established in the city of Philadelphia, with a salary of $10,000 yearly.

Dr. John J. Healy died at Philadelphia on May 7, in his fifty-fourth year. He was graduated from the medical department of the University of Pennsylvania in 1875.

Washington Franklin Anderson, for forty-six years a practitioner of medicine and surgery in Salt Lake City, Utah, died at his home in that city April 21, 1903. He was born in Williamsburg, Va., January 6, 1823, graduated from the University of Maryland in 1844, and for three years prior to graduation attended the clinics of the Baltimore Alms House Hospital, where he made original investigations into the pathology of remittent and typhoid fevers, his work being greatly facilitated by the large amount of clinical and pathological material of that institution. He established himself in general practice in Yorktown, Va., where he remained two years, and in 1849, attracted by the gold excitement in California, he removed to the Pacific Coast and practised his profession in Yolo County, California, for five

years. In 1857 he came to Salt Lake City, where he had been actively engaged in the practice of medicine and surgery up to the date of his death. He performed probably the first operations of lithotomy and ovariotomy in the then Territory of Utah. From 1857 to 1867 Dr. Anderson served as surgeon of the Utah Militia; was a member of the Utah Legislature in 1860 and 1861, and in 1876 helped to organize, and was elected the first president of, the Salt Lake Medical Society. In Dr. Anderson was seen that rare type of physician and gentleman which we usually associate with the physician of the "old school." He always had the highest regard for his profession, which his long term of service never diminished, and the uniform courtesy, gentleness, and sympathy which he invariably showed to the sick, endeared him to the hearts of all, as his ready efficiency and broad experience at the bedside commanded for him the confidence of all.

Francesco Colzi.—There appears in the *Lancet*, April 25, an account of the sad death of Francesco Colzi, one of the greatest surgeons in Italy. The Italian correspondent of the *Lancet* at Florence sends the description of the closing scene, which is both interesting and somewhat curious. A part of this is as follows: "Francesco Colzi, after a heroic struggle of ten days' duration, succumbed on April 4 to the terrible gunshot wound received in circumstances already made known to the readers of the *Lancet*. For some seventy-two hours the skilful medication of the fractured arm and lacerated axilla seemed to justify the abstention from amputation—the course approved by the eminent consultant, Professor Bassini of Padua. Bulletins were issued night and morning to meet the solicitude of the sympathizing public, from the King and Court of the quirinal downward, and the tenor of these, while not sanguine, could not be called discouraging. But by March 30, when gangrenous points began to declare themselves, the thought of saving the arm had to give way to that of saving life itself, and after a long consultation, held before Professor Bassini could arrive from Padua, it was decided to perform the amputation which Professor Colzi had counselled from the first, At the professor's own request the operator was his old friend and favorite pupil and clinical assistant, Dr. Stori, who proceeded with great skill to remove the arm just above the level of the fracture. The operation, which was performed without anæsthesia was an admirable specimen of the surgeon's art, and the subsequent medication seemed to give fresh assurance that the precious life might be preserved. The prognosis was further reinforced by the indomitable pluck, not to say vivacity of the patient himself, who, contemplating his lost arm, said: "E dopo? che farò per occupare il tempo? Anderò a studiare chimica nel gabinetto del Professore Piccini" (And then, What shall I do to employ the time? I'll go and study chemistry in Professor Piccini's laboratory). Tetanus, however, quickly set in, and Professor Colzi lasted but a short time after the operation.

Professor Colzi was born at Mousummano in Tuscany in 1855, received his education at the University of Pisa and at the Instituto di Studi Superiori at Florence, and graduated with great distinction in 1877. In 1879 he became Assistant in Surgery at the Hospital of the Santa Maria Nuova, and from 1883 to 1886 filled the post of assistant dissector in the Cabinet of Pathological Anatomy. He finally succeeded Dr. Corradi as professor of surgery in the Florentine School.

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent.)

HOSPITAL AMALGAMATION—KING'S FUND—ARMY ADVISORY BOARD—DESTRUCTION OF NETLEY SCHOOL—ABANDONMENT OF ANTI-TYPHOID INVESTIGATIONS—CANCER AND NERVE AREAS—U. S. PROFESSORIATE—TRYPANOSOMIATIS—MAJOR DANIEL'S EXPEDITION ON LEPROSY, ETC.—SIR HENRY NORBURY—RECENT DEATHS.

London, May 2, 1903.

Hospital distribution still occupies public attention. Amalgamation has received a decided impetus, for the Council of the King's Fund made a definite offer to the orthopedic hospitals to join their forces. There are three of them. The Royal, the unsavory history of which you know; the National, which is above reproach in any point, and the City, a much less important institution. The offer of the Fund was to the three, but the last named seems to have stood out to maintain its local position in the city. It was founded about 1850 or 1851 by the late Mr. Chance, who was greatly respected not only as a surgeon, but as a ripe scholar, and especially a Hebraist. He took great interest in the institution, which for many years depended on his work. Since his death it has made little progress. The offer of the King's Fund has now been made to the two West End hospitals and practically accepted by their managers. The Royal, which, as I told you, so lately sold its splendid site for what many consider an inadequate price, is to join the National, which has been lately enlarged, and the United institution is to receive from the King's Fund £7,500 toward the building and a subsidy of £1,500 toward maintenance.

It seems quite possible that this action of the Fund may prove a step toward its obtaining more control over our hospitals than the mere distribution of its income confers. If so, it remains to be seen whether the change will be beneficial. There are many difficulties to be encountered in any attempt of the kind—some of which I formerly indicated to you—but perhaps they may not prove insuperable. Certainly there are other special hospitals which might well be amalgamated, and as the King's Fund possesses the power of the purse as well as great social influence, it may be able to accomplish the task.

In connection with this subject a significant article has appeared by the Secretary of the King's Fund, Mr. J. G. Craggs, discussing the municipalization of hospitals in the event of complete failure of our present system. Comparing the cost of the Asylums Board's hospitals he argues that to throw all the burden on the rates would about double the amount spent upon them. Exception may be taken to his estimate, for he is comparing things which differ in many respects, but no one can doubt that the cost would be enormously increased, and another rate as high as that for education would prove intolerable. Perhaps, however, Mr. Craggs only raises this bogey to frighten the public into more liberal subscriptions; for not yet, I think, is London prepared to write ichabod where hitherto the inscription has been "supported by voluntary contributions."

The numerous changes that are being carried out in the Army Medical service are provoking very diverse criticisms. The rage that possesses the war minister for reorganization lays him open to opposition from various points of view, and he is being reminded that alterations are not always improvements. The institution of an "advisory board" was favorably received by the press, but those behind the scenes were doubtful whether it would prove useful. Many of the doubts have proved to be well founded and the board has at present failed to satisfy any one.

It was quite a shock to many when the school at Netley was abolished by, at is were, a stroke of the pen, though there were not wanting many others who expected much from the transfer to London. Nevertheless regret was felt in most quarters, even where the advisability of removal was admitted. The researches carried out at Netley were of the highest order, and the instruction given in the school and the hospital can scarcely be replaced even in London. But the board decided the matter, and instead of the four months' scientific training in the Netley School and clinical work in the Netley Hospital, which all medical officers obtained on entering the army, two months at the Embankment Laboratories and two at Aldershot for military training have been substituted. This certainly seems a strange way to improve the medical officers' education, and looks like the advice of the civilians on the board, considering how long the military men maintained that doctors were not soldiers. Quite lately it has been urged in *Nature* that the civilian element of the Advisory Board is "out of touch with and out of sympathy with the prog-

ress of medical research." I rather think it is not the civilian element alone which deserves this condemnation. The whole of the Medical Advisory Board of the War Office is to blame. Its want of appreciation of the value of research is aptly exemplified in a precipitate abandonment of anti-typhoid inoculation in face of the experience of the South-African war, which has once more read the terrible lesson that typhoid fever is more destructive to armies in the field than all other dangers. One would have supposed that, at least, Professor Wright's services would have been retained to complete the researches which have proved so important in this field, but it appears that the Advisory Board failed to secure them if it did not purposely make his position untenable. I am not prepared to say that Professor Wright's anti-typhoid vaccine is as efficacious as he thinks, or as many hope, but I suggest that a full explanation should be given of why the promising fruits of this and other researches at Netley should thus be flung away.

A possible relationship between carcinoma and nerve or trophic areas was the subject of a communication to the Pathological Society on the 7th inst. by Mr. G. Lenthal Cheatle, C.B. He thinks that a considerable proportion of cases indicate such a relationship. Consequently the extent of those areas should be considered in marking out incisions when removal of cancer is contemplated; but he would not detract from the importance attached to the lympathic pathways of distribution; he would merely add another factor. Further, he thinks the nerve influence in the area may directly or indirectly determine the incidence of cancer within such areas. He showed a number of lantern slides of rodent ulcer and cancer more or less limited to the area of supply of certain nerves and called attention to the central connection between the fifth cranial, the glossopharyngeal and pneumogastric nerves. He thought the cases showed nerve areas so distinctly mapped out that the point could not be overlooked. The areas occupied could not be solely determined by developmental or anatomical conditions, but were perhaps due to some direct or indirect nervous or trophic influence.

Some persons maintain that we have too many medical schools in London. In comparison with America, we have but few. Some statistics quoted here from the journal of your association have rather surprised me. It is said that there are 156 medical colleges in the United States. That accounts for the numerous persons on your side who have the title of professor. The number of teachers in the 156 colleges is given as 6,776; the number of students as 27,501, of whom 5,002 graduated in the year 1901–2. It would thus appear that each teacher only had four students and qualified 0.738 of a graduate in the academic year. Truly American students do not lack instructors.

A report has been received from the expedition of the Liverpool Tropical School, which seems to show that success is likely to attend the investigation on trypanosoma. A house has been inoculated, and a species of fly which had fed on it was infected.

Major C. Daniels of the U. S. Army is in London organizing an expedition to New Guinea and the Solomon Islands for the study of leprosy and cancer. Dr. Seligmann, pathologist of St. Thomas's hospital, will accompany this expedition, for the cost of which the Major is, I hear, responsible.

The term of office of Sir Henry Norbury, K.C.B., as Director-General of the Medical Department of the Navy is to be extended.

Deputy Surgeon-General J. F. Shekleton, F.R.C.S.I., who died on the 15th inst., aged eighty-three years, joined the Indian Medical Service in 1845. He served through the Punjab campaign, 1848–9, and received the medal and two clasps. Later he was employed as chief assayer at the Calcutta mint. After his retirement he settled at Clifton, and for several years devoted much time and energy to the management of the Bristol Royal Infirmary.

The death is announced of Brigade-Surgeon R. T. Lyons (retired) of angina pectoris, in his sixty-eighth year. He joined the service in 1860 and took part in several expeditions, was in the Afghan war, 1878–9, and in Egypt 1885 (Suakin). He received medals and other distinctions.

Dr. Edward Adamson, J. P., of Rye died suddenly on the 18th ult. He was taken ill at church and on his way home fell down. He died soon afterward.

On the Surgical Treatment of Localized Spasmodic Affections, Spasmodic Torticollis, etc.—A. Chipault declares that in spasmodic torticollis and in spasmodic adductions of the thighs, there is indication to interrupt all communication between the contracted muscles and the nervous centers. This manipulation is possible, even easy and without danger, from the operative point of view. It has proved its superiority over other therapeutic methods, especially in complete nerve resections and tendon sections. The effect obtained is not immediate, but progressive.—*La Médecine Moderne*, April 22, 1903.

TREASURY DEPARTMENT — BUREAU OF PUBLIC HEALTH AND MARINE HOSPITAL SERVICE.

WASHINGTON, April 30, 1903.

A BOARD of officers will be convened to meet at the Bureau of Public Health and Marine Hospital Service, 3 B Street, S. E., Washington, D. C., Monday, June, 15, 1903, for the purpose of examining candidates for admission to the grade of assistant surgeon in the Public Health and Marine Hospital Service of the United States.

Candidates must be between twenty-two and thirty years of age, graduates of a reputable medical college, and must furnish at least two testimonials from responsible persons as to their professional and moral character.

The following is the usual order of the examinations: (1) physical; (2) oral; (3) written; (4) clinical.

In addition to the physical examination, candidates are required to certify that they believed themselves free from any ailment which would disqualify for service in any climate.

The examinations are chiefly in writing, and begin with a short autobiography of the candidate. The remainder of the written exercise consists in examination of the various branches of medicine, surgery, and hygiene.

The oral examination includes subjects of preliminary education, history, literature, and natural sciences.

The clinical examination is conducted at a hospital, and when practicable, candidates are required to perform surgical operations on a cadaver.

Successful candidates will be numbered according to their attainments on examination, and will be commissioned in the same order as vacancies occur.

Upon appointment the young officers are, as a rule, first assigned to duty at one of the large marine hospitals, as at Boston, New York, New Orleans, Chicago, or San Francisco.

After five years' service, assistant surgeons are entitled to examination for promotion to the grade of passed assistant surgeon.

Promotion to the grade of surgeon is made according to seniority, and after due examination, as vacancies occur in that grade. Assistant surgeons receive $1,600; passed assistant surgeons, $2,000; and surgeons, $2,500 a year. When quarters are not provided, commutation at the rate of $30, $40, and $50 a month, according to grade, is allowed.

All grades above that of assistant surgeon receive longevity pay, 10 per cent., in addition to the regular salary for every five years' service up to 40 per cent. after twenty years' service.

The tenure of office is permanent. Officers traveling under orders are allowed actual expenses.

For further information, or for invitation to appear before the board of examiners, address

WALTER WYMAN, M.D.,
Surgeon-General, Public Health and Marine Hospital Service, Washington, D. C.

Ureteroscopical Diagnosis and Treatment of Chronic Ureteritis.—Georges Luys believes that ureteroscopy ought to be considered as a method giving infinitely better results than any other method of investigation of the ureter. By it, polyps, vegetations, and papillomatous growths in the ureteral mucosa can be recognized; stenoses, characterized by hard infiltration of the mucosa, which hinders the walls of the canal from coming together, lesions of Littre's glands, lesions of the valvular folds. Ureteroscopical treatment consists in the destruction with fine points of the galvano-cautery of the foci, which keep up indefinitely chronic ureteritis.—*La Presse Médicale*, April 22, 1903.

Cutaneous Pigmentations of Genital Origin in the Woman.—Paul Dalché and Ch. Fouquet present this very interesting paper and cite various illustrative cases. One of these was a patient aged fifty-seven years who was afflicted with black pigmentation. Until the age of fifty-three years, she had always enjoyed good health. But at that time she began to grow thin, losing her appetite and becoming weak and languid. There was no organic lesion discoverable to explain her condition. There were two striking phenomena in her illness. One was the frequent outbreak of pustules which, without cessation, developed on the fingers and sometimes on the body; the other was a general discoloration, more pronounced, on the hands fingers and thighs. Although she was very careful in her personal hygiene, she noticed that her linen became quickly soiled. Her hands, principally at the finger-tips, were visibly black, not uniformly, but in places. In vain she washed them twenty times a day—the pigment reappeared. Menstruation had ceased one or two years before. This affection was rebellious to treatment.—*La Gynécologie*, February, 1903.

Progress of Medical Science.

The Boston Medical and Surgical Journal, May 7, 1903.

X-Light in Anthropometrical Signalment.—William Rollins says that any procedure which makes the measurement of criminals more exact must be valuable. Such a one is that of making *x*-light photographs of the bones. He estimates that this method at least doubles the accuracy with which measures of the hand can be taken, and by enabling other measures of the feet, besides the length to be taken; it allows at least four times as many persons to be identified as at present, though the real number will be found to be much greater. In cases of bodies burned or decomposed before they are discovered, the method would have some advantages over any that has been proposed. In other cases when only some of the parts of the body are found, as for example, a hand or a foot, the method alone might lead to identification. The author has designed and constructed apparatus for conducting these *x*-light photographic anthropometric signalments.

Brachial Paralysis, Post Narcotic.—F. J. Cotton and S. W. Allen conclude from a case which they report that paralysis of all or part of the muscles supplied by the brachial plexus with some sensory involvement, is not very uncommon after narcosis, though rarely mentioned. Its cause is not toxic but mechanical. It occurs only when the arms are long held above the head or lie in abduction—never if they lie flexed on the chest. The mechanism is a pressure on the nerve roots, probably between the clavicle and the muscles over the transverse processes of the cervical vetebræ, or from stretching over the head of the humerus in abduction. The trouble is essentially functional without known lesions. The lost function returns *in part* very early. Total recovery is often long delayed, but apparently is to be counted on. In view of the risk of paralysis, the arms of a patient under ether should always, when possible, be flexed with the hands on the chest. If other positions are unavoidable, they should not be continued long without change.

New York Medical Journal, May 9, 1903.

Report of a Case of Pulsating Empyema Necessitatis, with Three Strongly Pulsating Tumors.—F. P. Henry gives a detailed account of the case which was seen over twenty years ago. Meagre notes were then published in a volume of society transactions not accessible to the general reader. The patient was a woman of thirty years. On the left side of her chest were three strongly pulsating tumors; one in the mammary region, of about the size of half a large orange; a second, much smaller and of conical shape in the left anterolateral region, *i. e.* in the eighth intercostal space in a line with the anterior axillary border, and a third, the largest of the three, in the left posteroinferior region, its long diameter, about four inches, corresponding with that of the vertebral column. The large anterior tumor contained air and fluid; the two others only fluid. The case was operated on and was known to be alive and well one year thereafter. The subsequent history is unknown. Henry adds references of fifteen additional cases of pulsating pleurisy to the sixty-eight tabulated by J. C. Wilson in 1893.

Astigmatism Cured by Corneal Trauma.—The patient of P. Fridenberg was a physician who was struck in the eye by a small piece of wood known to small boys as a "cat." The detailed ophthalmological condition before and after the injury are stated. The author considers the mechanism of the cure to be exactly that which produces astigmatism after cataract extraction, viz., the flattening of the corneal curve from scar contraction. As the corneal section is usually upward or downward, the vertical meridian is affected, becomes flattened, requires a convex cylinder, axis horizontal, to increase its refraction; we have astigmatism against the rule. This decreases within the first month or two after operation, by which time an irreducible minimum is found, the amount of which depends upon the extent, position, and manner of healing of the corneal section. In the case reported there was no actual section, merely a superficial —although extensive—incision of the cornea. The astigmatism was corresponding y slight, and, by a most peculiar chance just sufficient to neutralize a preexisting inequality of curvature.

Journal of the American Medical Association, May 9, 1902.

Diagnostic Value of Blood-pressure Determinations in the Diagnosis of Typhoid Perforations.—G. W. Crile states that the highest systolic pressure in uncomplicated cases and with normal arteries, as measured by a Riva-Rocci sphygmomanometer in 115 cases of typhoid, was 138 mm. mercury; the lowest, 74 mm.; the mean in the first week was 115; the second, 106; the third, 102; the fourth, 96; the fifth, 98. In twenty cases of acute peritonitis, recorded by the same observer with the same instrument in otherwise similar cases, the highest systolic pressure was 208 mm. mercury; the lowest, 156; the mean, 166 mm. The mean pressure of all the typhoid was 104 mm. He then states his personal experience to the effect that in five cases diagnosticated as typhoid perforation in which blood-pressure determinations were made, four were verified either by operation or autopsy. The fifth case, a typical one, was not operated on. Brief notes are given of the five cases, but results of operation are not stated.

Philadelphia Medical Journal, May 9, 1903.

Novelties in the Physical Treatment of Skin Diseases.—L. Freund says that diseases like lupus, epithelioma, favus, and sycosis, which were formerly considered almost incurable, have been healed by new radio-therapeutic methods in an incredibly short time, without pain, and without causing patients the discomfort of bandages, dressings, or long sojourn in bed, necessitated by some of the earlier methods of treatment. Dermatologists have also taken precedence in the other branches of physical therapy, as shown by the wonderful results of the water-bed, the Ehrmann cataphoresis, electrolysis, the therapeutic employment of high and low temperatures, etc. The author reports the results of some of his experiments with Röntgen rays in epithelioma and lupus. He has also discovered by experimentation, that the rays of sunlight, of large wave length (heat rays), possess no bactericidal influence. On the other hand, they do exert a favorable influence in some skin affections, as acne vulgaris, leg ulcer, etc.

Medical Education in the United States.—Frank Billings in his address delivered at the fifty-fourth annual session of the American Medical Association at New Orleans, May 5–8, reviews the subjects of the medical schools of the country, Scientific Medicine, Methods of Medical Education, Applied Medicine and Surgery, Education Preliminary to Medical Study, the University Medical College, the Outlook of medical education in the United States, Medical reciprocity between the States of the Union, and the influence of the American Medical Association. The latter, he says, should stand for, and should use its whole power to improve medical education in this country. It should take as its ideal and standard of medical education the University Medical College, with all the name implies in regard to the fundamental medical sciences, and to the clinical branches. It should use its influence to drive out of existence those proprietary medical schools which are conducted solely as money-making institutions. These measures cannot be accomplished at once, but medical science demands it, the profession demands it, the people demand it, and look to the American Medical Association as the chief influence which shall accomplish this end.

Medical News, May 9, 1903.

On the Resemblances of Malignant Endocarditis to Typhoid and Paratyphoid Infections.—Henry L. Elsner declares that, considered collectively, typhoid fever shows a surprisingly infinitesimal number of permanent heart lesions during the acute febrile period, or following. Hence, with evidences of endocarditis and the typhoid condition, we are justified in assuming that the disease is not typhoid fever. To make the diagnosis positive ante mortem, we must have the presence of physical signs referable to the heart, and these we have in the majority of our cases before death. However, the endocardium may be plastered with vegetations without giving rise to physical signs. The presence of embolic infarct is a valuable diagnostic fact.

Intraperitoneal Ligation of External Iliac for Femoral Aneurysm.—William B. Crawford reports this case. An incision three and one-half inches long was made through the skin to the external oblique. After the operation the leg was elevated and continuous heat applied, combined with Tufnell's treatment. Primary union took place. Pulsation was felt in posterior tibia artery on the third day. The foot and leg remained cold for five days, and for twelve days after were colder than the leg of the opposite side. The heat and elevation was continued constantly for seventeen days. Three weeks after operation the tumor had decreased to one-half of its original size and no pulsations could be felt. Two weeks later, examination revealed a small tumor one-third of original size, and with no pulsations. The circulation in the foot was good.

American Medicine, May 9, 1903.

Emansio Mensium.—William Himmelsbach reports two cases. One is a patient of twenty-three years who has never menstruated. There is an infantile uterus.

Aside from slight hæmoptysis at long intervals, she has been perfectly well. The second patient menstruates once or twice a year, but has gone fourteen months without losing a drop of blood in any way. She is well nourished.

An Obstetric Suggestion.—Arthur Devoe offers several considerations for the promotion of infantile life: (1) Stretching the sphincter ani gives immediate aid to respiration at a moment of partial or advanced asphyxiation, which is present in so many of the new born. (2) For this purpose the little finger may be quickly cleansed and oiled, and the operation done for the child while it is in a more or less anæsthetic condition; later on the operation becomes more objectionable as causing more suffering. (3) This routine supplies early the important knowledge as to whether a competent sphincter and anal opening exist. (4) As this stretching of the sphincter is an important aid in establishing respiration, so also it may be considered a help to peristalsis and the due establishment of intestinal function.

Münchener medicinische Wochenschrift, April 21, 1903.

Cardiac and Cardiac Apex Impulse in Aortic Insufficiency.—Giovanni Galli shows that these impulses are not always increased in aortic insufficiency, as has been generally supposed, and hence that their failure to be increased does not necessarily negative a diagnosis of aortic regurgitation. This hold true whether or not this lesion be complicated with mitral insufficiency. Two cases are reported. The first went to autopsy and showed both aortic and mitral insufficiency. Here the cardiac impulse was increased, but not the cardiac apex impulse. The second case was a pure aortic regurgitant lesion, and neither one of these impulses were increased. It is probable that the absence of these increased impulses is due to a marked decreased functional activity of the cardiac muscle, as the result of which it is not able to respond to the increased demands made upon it in the presence of these lesions.

Blood Changes after Extirpation of the Spleen.—E. Rautenberg reports the following blood changes found in a case after the extirpation of a sarcomatous spleen. These changes were persistent for five months following the operation. The number of red blood cells was distinctly increased, the increase being first noticed after the operation. The percentage of hæmoglobin was not materially altered. For four weeks after the operation the total leucocyte count was doubled (increasing from 5,000 to 10,000). It then gradually receded, remaining at 7,000. The polymorphonuclear neutrophilics were at first markedly, both relatively and absolutely, increased. Later they were reduced to 60 per cent. The lymphocytes became permanently increased, being raised from 19 per cent. to 30 per cent. The eosinophiles were also permanently augmented, being increased from 2 per cent. to 8 per cent. These changes deviate from those previously reported under similar conditions in the following respects: (1) The permanent total increase in red blood cells. (2) The absence of hæmoglobin variations. (3) The early and permanent increase in eosinophiles.

The Treatment of Laryngeal Tuberculosis.—E. Kronenberg, as the result of his experience, says that operative treatment is only especially indicated in those cases in which the general condition is good and in which it is certain, or at least extremely probable, that the tuberculous lesions can be removed in their entirety. If such a complete removal is not possible and operation is only to be considered for the suppression of troublesome complications, or for the removal of tissues which are a hindrance to other therapeutical measures. In conducting such operations laryngotomy is seldom to be advised. The proper method is operation through the mouth. None of the much-recommended escharotics have a specific influence upon this condition, and the galvano-cautery is to be preferred to any of them. After all is said and done, the most important means in the treatment of laryngeal tuberculosis are those which seek to improve the general condition and bring about a spontaneous recovery. In the present want of any specific agent against tuberculosis, climatic and dietetic measures yield the best results.

Deutsche medicinische Wochenschrift, April 9, 1903.

Phenylhydraz in Sugar Test.—E. Riegler gives a new test for glucose, which is of advantage because of its easy execution and its great sensitiveness, it demonstrating the presence of glucose when in a .05-per-cent. solution. It is performed as follows: two solutions are made, the first is composed of 1 c.c. of the fluid to be tested, 10 c.c. of water, and a small crystal of phenylhydrazin: the second is made by dissolving 1 gm. of sodium hydroxid in 10 c.c. of water. These solutions are at once mixed and shaken, when, if sugar (glucose) is present in at least the above percentage, a beautiful reddish violet color appears.

Toxic Cardiac Myolysis in Diphtheria.—Hans Eppinger says that post-diphtheritic cardiac paralysis is due to a myolysis of the heart muscle caused by the action of the diphtheria toxin. Extensive macroscopical and microscopical examination of the heart muscle of those dead from post-diphther tic cardiac paralysis has shown that the individual fibers of this muscle are separated from one another and are undergoing a peculiar degeneration. Similar appearances are not found in the cardiac muscle of those dead from other diseases, and it seems certain that they are due to a specific action of the diphtheria poison.

Deutsche medicinische Wochenschrift, April 16, 1903.

Pyramidon in the Treatment of Typhoid Fever.—Valentini has treated nineteen cases with this drug, of which twelve were severe, four moderate and three mild cases. Two were fatal, one from a complicating pneumonia and the other from cardiac weakness. By the administration of pyramidon every two hours, day and night, in typhoid fever the temperature may be rapidly reduced to the normal, while the pulse and general symptoms are favorably influenced. No unfavorable action of the drug was observed. The dose for children is .1 to .2 g. every two hours, for adults .3 to .4 g. at the same interval. This should be continued until the temperature reaches normal or below, which takes place in a few days. The interval is then gradually lengthened, provided no rise of temperature takes place, but the administration is not discontinued until the fever has permanently disappeared.

Berliner klinische Wochenschrift, April 20, 1903.

Immunity in Recovery from Pneumonia.—F. O. Huber thinks that recovery from pneumonia is due to the production of a bacterial immunity, or, in other words, to the presence of specific immune bodies. The action of such immune bodies upon the pneumococci is such that the negative chemotaxis which exists between them and the leucocytes is changed to a positive chemotaxis, which results in a marked phagocytosis. The moment that this positive chemotaxis appears corresponds with the time of the crisis. This view is supported by the recent theories of immunity as advanced by Ehrlich and Metschnikoff, and furthermore by the microscopical examination of pneumonic sputum following the crisis, which shows, so far as it has been carried out, the presence of many pneumococci within the leucocytes, while previous to the crisis such an intracellular location is not found.

Mesotan, an External Anti-rheumatic.—K. Liepelt has treated thirty cases of acute articular rheumatism with mesotan, which is a preparation of salicylic acid. The involved joints were thoroughly massaged with the substance three times daily and then covered with cotton. In every case before treatment was begun the urine was tested with ferric chloride for the presence of salicylic acid, and only those cases were chosen for treatment in which the test was negative. In all the cases treated the urine gave a weak salicylic reaction within two hours after the first application, and within four hours this reaction became pronounced. In the vast majority of the cases a rapid improvement was noted both in the local and general symptoms. Such an improvement was usually permanent, but relapses occasionally occurred. These relapses, however, speedily responded to the same treatment. In many cases morphine or the various analgesics were used in addition to the mesotan, but not a few were treated with the latter alone. A few cases showed no improvement as the result of the applications. The best results were obtained in recent cases of polyarthritis rheumatica in which, in addition to the mesotan aspirin in .5 g. doses was given three times a day. Mesotan was also tried in the various forms of muscular rheumatism with very fair result.

French Journals.

Neoplasm of the Pylorus.—P. Courmont and André describe the case of a patient who was operated on two months before for a neoplasm of the pylorus. The results was most gratifying. The patient, who had suffered from anorexia, with especial distaste for meat, has recovered his appetite. He took on flesh, and his red blood-corpuscles increased to 500,000. The chemical condition of his stomach was not abnormal. This improvement is due chiefly to the disappearance of the mechanical obstacle which caused the stenosis of the pylorus, disturbing the digestive functions and favoring gastric fermentations.—*Lyon Médical*, March 1, 1903.

Suppurative Hydatid Cyst of the Mesentery.—Vincent relates the history of a woman of sixty years who was attacked with a sudden violent pain in the right flank with peritoneal symptoms. On palpation tumor was felt in this region. It had no connection with the genital organs nor with the biliary apparatus. Lumbar

incision was practised, and transperitoneal operation performed. The wall of the cyst was sutured to the skin; part of the wall was resected. A large quantity of purulent liquid escaped. Enucleation was done. It was an hydatid cyst, which the writer believes was located in the mesentery.—*Revue de Chirurgie, April, 1903.*

The Murmur of Cardiac Asthenia.—Lamacq concludes that the brief presystolic murmur, without propagation, whose seat is at the center of the surface of cardiac projection, is a sign of fatigue of the heart. It is due at the beginning of each systole to a very brief functional insufficiency of the valves. Spasmodic mitral contraction is inadmissible. This murmur, with its special characteristics, will be recognized at the beginning of all fatigue of the heart, at the beginning of myocarditis, of pericarditis, in the majority of infectious maladies, and finally in the simple nervous conditions: emotions, fear, etc. The heart should always be auscultated, not only from the four classical points, but also in the mesocardiac zone.—*Archives Générales de Médecine*, March 3, 1903.
